FLEETWOOD.—It has been decided to obtain further tenders for the works in connection with the electric light.

HALIFAX.—Last week a Local Government Board inquiry was held relative to an application by the Corporation for powers to borrow £30,000 for electric lighting purposes. The proposal was opposed by the Halifax Mutual Electric Light and Power Company (Limited), who claim that they have been unfairly dealt with by the Corporation in connection with their electric lighting undertaking. Evidence was given by Mr. T. P. Wilmshurst, electrical engineer to the Corporation, who said he had prepared a scheme and estimate in accordance with the Provisional Order. He had received certain tenders in connection with the work, all considerably below his estimate. His scheme had had the approval of Mr. W. H. Preece, who had visited the sites suggested for the central station. The cost of laying the mains, &c., throughout the compulsory area would be about £27,000, and the plant estimated for would be sufficient to provide 10,000 lights, but mains sufficient to supply 30,000 would be laid. At present it was proposed to expend £9,000 on mains, but the area was an extensive one. With regard to the opposition of the local Company, the Town Clerk stated that the question of the electric lighting being in the hands of the Corporation was made a test at the last municipal election, and those gentlemen pledged in regard to it were returned. At the close of the inquiry the Inspector was understood to agree to the Town Clerk's view that the Board had practically already sanctioned the Corporation's scheme.

HUDDERSFIELD.—£5,000 has been taken on loan from the Borough Fund by the Electric Lighting Department of the City Council. An extension of the electric supply main for a further distance of 25 yards along Queen-street, South, to supply Milton Church, has been decided upon, and the Masonic Hall is also to be connected. The Council have received an offer from the Edison and Swan United Electric Light Company (Limited) to be allowed to exhibit electric light fittings and apparatus at the Corporation's works at the Company's expense, but the offer was declined on the ground that it would be unfair to other firms in the same line of business. The decision of the Council in the matter met with some opposition, many of the councillors considering that the electric light being new to the town, it would have given intending purchasers of fittings an opportunity of viewing the latest design.

JOHANNESBURG.—A correspondent informs us that electrical business at Johannesburg is very dull, and that he "would not advise any young fellow to go to Johannesburg in anticipation of electrical work, as there are already too many electrical engineers in the district."

KELSO.—Newton Don, the residence of Mr. C. B. Balfour, has been completely installed with the electric light, power for which is supplied from the Lynn waterfall; 300 incandescents are used, and the current is also employed for domestic purposes. The work has been carried out by Messrs. A. A. C. Swinton and Co.

KILLARNEY.—The Asylum Board, at their last meeting, passed a resolution approving of the introduction of the electric light in lieu of gas, and decided to advertise for tenders for an installation of 450 lights, on a specification to be drawn up by the Engineer to the Board of Control, who are to carry out the work. An amendment calling upon the Board to abandon all proceedings in connection with the electric light was defeated.

Digitized by Google

LEICESTER.—A public meeting promoted by the Leicester Ratepayers' Association was held last week in the Market-place, to protest against the borrowing by the Corporation of £50,000 for the purposes of the electric light supply. Resolutions supporting the object of the meeting were duly carried, and the action of the Association approved. "Other speeches (the *Daily Post* says) followed, and a collection having been announced, the meeting began to disperse."

MONTROSE.—It has been decided to build a new chimney stack, and to put down mechanical stokers, fuel economisers, and other improvements, at the Montrose Asylum, at an estimated cost of between £700 and £800. This additional plant is chiefly required in connection with the electric light.

NEWCASTLE-ON-TYNE.—At the meeting of the Town Moor Management Committee on Tuesday, it was decided to ask the Town Council's sanction for lighting by electricity the proposed fountain in the centre of the lake in Hoyle's intake.

PARTON.—It is rumoured that the Lowca Engineering Company contemplate laying down plant for the production of the electric light, and that they will offer to supply the electric light in the district.

RICHMOND (SURREY).—A circular has been issued by Messrs. Latimer Clark, Muirhead and Co., the contractors for the electric lighting work, to the effect that the electric current will be turned on from the new central station on October 1st, and asking those who are desirous of making arrangements for wiring their premises to send in their applications without delay.

SOUTHAMPTON.—In the report of the Works Committee, just presented to the Harbour Board, it is stated that the electric crane recently erected is giving the utmost satisfaction.

WORCESTER.—The Board of Guardians last week discussed the decision come to by the City Council to adopt the electric light, and it was suggested that the Guardians should reconsider their decision and adopt the light for the new workhouse. The matter is to come up for discussion at a future date.

PATENT RECORD

A record of Applications for Patents and Patent Specifications Published is compiled for this journal by MR. J. C. CHAPMAN, *Fel. Chartered Inst. Patent Agents, of 70, Chancery-lane, W.C., from whom any information on the subject may be obtained.*

APPLICATIONS FOR PATENTS.

NOTE.—*The Specifications of Applications for Patents are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions, or where complete specification accompanies application an asterisk is suffixed.*

July 28, 1893.

14,556. R. T. PRESTON and A. B. GILL. London. Improvements in apparatus for raising and lowering bodies applicable, for instance, to electric and other lamps and railway carriage and other blinds, and to hoisting gear.

14,562. H. W. RAVENSHAW and L. B. ATKINSON. London. Improvements in alternate-current dynamos and synchronising motors.

July 29, 1893.

14,628. F. HURTER. London. Improvements in or connected with cells or batteries for use in electrolysis.

16,335A. E. M. HARRISON. London. Improvements in induction coils. [Date claimed under Patents Rule 19, September 13, 1892.]*

16,335B. E. M. HARRISON. London. Improvements in magneto electric generators. [Date claimed under Patents Rule 19, September 13, 1892.]*

16,335C. E. M. HARRISON. London. Improvements in electric bells. [Date claimed under Patents Rule 19, September 13, 1892.]*

July 31, 1893.

14,640. A. R. UPWARD. London. A form of water actuated electric switch.

14,643. P. A. BEBOUTOFF. Middlesboro'. Beboutoff's automatical and electrical pile or monkey driver.

14,647. C. ANDERSON. Leeds. Improvements in apparatus for working electric tramways by means of underground cables.

14,664. J. A. KINGDON. London. Improvements in electromotors for alternating currents.

14,685. L. H. HORDERNE. London. Improvements in and relating to apparatus for heating and warming by electricity.

August 1, 1893.

14,715. E. G. HARCOURT. Birmingham. Improved bell-pull arrangement for electric bells.

14,742. F. W. PLUMSTEAD and H. H. HUNTER. London. Improvements in or appertaining to electric light fittings.

14,756. A. G. BROOKES. London. Improvements in dynamo-electric generators and motors. (H. J. Ryan, United States.)*

August 2, 1893.

14,816. A. A. LATEULÈRE. London. An improved electromotor for boats and like purposes.

August 3, 1893.

14,863. A. CAMPBELL. Londonderry. Improvements in electrical resistances.

14,868. J. THOMSON. Glasgow. Improvements in electricity meters.

14,910. P. JENSEN. London. A method of and apparatus for electrolytical decomposition while using quicksilver as cathode. (A. Sinding-Larsen, Norway).*

August 4, 1893.

14,953. T. B. SHARP. Birmingham. Improvements in regulating the supply of electricity to incandescent lamps.

14,966. E. MORWAY. London. Improvements in the construction of loud-speaking micro-telephones.

14,969. F. M. NEWTON and T. HAWKINS. London. Improvements relating to two-pole dynamos, motors, and the like.

14,997. E. EDWARDS. London. Improvements in electric contacts for telegraphic vibrators. (P. la Cour, Denmark.)

August 5, 1893.

15,025. F. A. J. FITZGERALD. Dublin. An electric plant protector.

15,034. T. J. GOUGH. Manchester. An improved electrical and clock-work combination apparatus for the recording of workmen's time and like records.

SPECIFICATIONS PUBLISHED.

All Specifications price 8d. each.

1892.

13,375. SPENCE. Electric meters, &c.

14,064. ALDRED. Electric current machine and motor.

15,066. WEBBER and NISBETT. Electrical cut-outs.

15,840. CROMPTON and POCHIN. Electric arc lamps.

16,571. WOODHOUSE and RAWSON UNITED (LIMITED) and RAWSON. Electric motors.

16,644. SIEMENS BROS. and Co. (LIMITED) (Siemens and Halske). Measuring electrical currents.

16,805. SCOTT. Electric search-light apparatus.

16,877. FORBES. Telephone signalling apparatus.

16,892. TOMMASI. Extracting, separating, &c., metals by electrolysis.

16,893. TOMMASI. Extracting, separating, &c., metals by electrolysis.

17,160. KINGSBURY (Western Electric Company). Telephone switchboard apparatus.

17,246. RAWLINS. Electric batteries.

1893.

519. LAKE (Weston). Electric resistance boxes.

6,975. BERRY and HARRISON. Electric circuits.

8,330. CAMPANY. Electric car brakes.

9,302. PREWITT. Contracts for electric railways.

9,353. BINSWANGER. Electric lighting, &c.

9,821. LAKE (Whitney Electrical Instrument Company). Galvanometers.

11,099. LAKE (Colby). Electric glow lamps.

11,578. THOMPSON (Coffin). Electrically welding metals.

11,608. MCELROY. Electrical heaters.

11,609. MCELROY. Electric switches.

11,680. SAUER and HENTZSCHEL. Electric alarm apparatus.

12,457. URQUHART and SMALL. Electric conductors.

COMPANIES' MEETINGS AND REPORTS.

The Oriental Telephone and Electric Company (Limited).

The thirteenth ordinary annual general meeting of this Company was held on Wednesday, at the Cannon-street Hotel, under the presidency of Mr. William Addison.

The SECRETARY (Mr. Alexr. B. Chalmers) read the notice calling the meeting.

The CHAIRMAN then said: Gentlemen, in moving the adoption of the report and balance-sheet, I am pleased again to be able to congratulate the shareholders on the steady increase in our business, although, as mentioned in the report, the depreciation in the value of silver has prevented our showing any great improvement in the net results of the year's working as compared with those of last year. However, in these times of commercial depression an increase in the amount of business done is in itself satisfactory, and it is solely owing to causes over which we have no control that the profits have not been proportionately better. You will see from the report that the appeal to the House of Lords has been allowed, and consequently there is a sum of about £13,000 owing by the holders

Digitized by Google

of Vendors' shares on account of interest payable to the holders of Ordinary shares during the first five years of the Company's existence. I may mention for the benefit of those who have not followed the matter closely how this litigation came about. It was in this way:—The question of the legal interpretation of a clause in the original agreement was raised by an eminent actuary some three years ago, who was consulted as to the relative values of Vendors' and Ordinary shares, and in consequence your Board was advised to commence a friendly action in Chancery for the purpose of getting an authoritative decision, and was prepared to accept such decision as final; but some of the holders of Vendors' shares, after waiting nearly twelve months, appealed. The Court of Appeal reversed the decision of the lower Court. As the two Courts differed, your Board had no alternative but to take the matter to the House of Lords for final decision. That decision we have now got, and litigation, which is always to be deplored except by the lawyers, has ceased. I am glad to inform you that after many representations to the Government of India, both on this side and in India, in regard to the competition of the Indian Telegraph Department, through that Department installing and undertaking to supply telephonic communication in districts for which they had granted licences to us, the Government has seen fit to withdraw from competition in these specially-reserved districts. It certainly did seem unreasonable that the Telegraph Department should compete with our subsidiary Companies and ourselves, and at the same time extract royalties from us. In looking at the profit and loss account, you will see that there is a balance of profit of £9,085. 5s. 11d., and adding to that £1,957. 16s. 4d. carried forward from last year, there is a sum of £11,013. 2s. 3d. to be dealt with. Now, the present Board have always in their minds their promise on taking office not to make a call if it can be avoided. To enable them to carry this out it is necessary to provide a substantial reserve fund for necessary and useful extensions, and for the demands of a growing business. We propose, therefore, this year to add a further sum of £2,500 to the reserve fund, which brings it up to £12,500, all invested in Consols, and, therefore, immediately available should money be required. The dividend now recommended is equal to £3. 12s. 2d. per cent. on the Ordinary shares. I do not know what more I can add to what I have already told you, and to what you will find in the report. Our business is sound and progressive, and I think all here will agree with me that the present balance-sheet is certainly the best that has hitherto been presented at any annual meeting of the Company. Before putting the resolution to the meeting I shall be glad to answer any questions.

Mr. HIBBERT said that it was now about fifteen months since they had heard anything from the Directors, and he thought that during that period the Board might have made some communication to the shareholders with regard to the lawsuit mentioned. He had no idea that any decision had been given against them or that there had been any appeal, and he thought that a circular might have been sent to the shareholders giving them this information.

A SHAREHOLDER remarked that this would have entailed expense.

Mr. HIBBERT said that the expense would not have been much. With regard to the balance-sheet, it was most favourable, no doubt, and their position looked very well in regard to the future. He could not understand how their shares were so low, because there was sufficient to pay a dividend of about 12 per cent. on the market value of the shares. It occurred to him that the market price of the shares was owing to the uncalled liability of 9s. a share, the shares being of £1, with 11s. paid. Surely there must be some means of getting rid of this liability, the Directors themselves having stated that they had no idea of making a call. He thought that the shares might be made into 10s. shares, and he commended this point to the Directors for their consideration. The revenue account stated "by net profit on working of the Company's exchanges," &c. He wished to know the actual profit on their exchanges, and where they where. He imagined that the principal part of their profit was derived from their shares in other companies, which was a considerable sum. With respect to the item in the balance-sheet of telephone patents and goodwill, £71,000, that was a very large amount, and he wished to know if there was any real value in their goodwill. He presumed, with regard to the next item of £34,924, that the expenditure had been on their own exchanges.

The CHAIRMAN: That gentleman who last spoke wants to know why we did not send out a circular giving the progress of the different appeals. I certainly cannot see the necessity of doing so, and I fail to see what good it would have done. We had three cases on, and to have sent out the information mentioned would have cost about £5 in each case.

Mr. HIBBERT thought that that would have been a very small amount.

The CHAIRMAN (continuing): The next question is as to reducing the liability on the shares. It has been our object, and it was the principal cause of this litigation to make all classes of shares alike. It was at the wish of one of the largest shareholders that we should take the first decision which we did, and he raised the question of the way of paying the dividend. There was a judgment one way and a judgment another way, and now the House of Lords have supported Mr. Justice Kekewich. All this litigation arose from our trying to have one class of shares, and trying to negotiate with the vendors for that purpose. Now we have this decision, I hope that we shall be able to come to some arrangement with that object.

Mr. KING asked whether it was meant to reduce the liability on the shares having 11s. paid up?

The CHAIRMAN: That has been our object all through—to reduce the liability and to have one class of shares. The profit on the Oriental exchanges was about £4,000. The value of the goodwill stands at £71,000. That represents our business. Unless we had had the goodwill we could not have carried on our business.

A SHAREHOLDER inquired the present value of the shares held in the subsidiary companies?

The CHAIRMAN: There is no market for them, and therefore they remain in the balance-sheet as they were. Their value has not decreased. I may say that much.

Mr. W. S. CUFF remarked that the Chairman had stated why the Directors had added to the reserve fund, and personally he approved their policy. He also considered that they were in a very much better position than they had been for many years now that they had settled the question which had been pending with the vendors. He wished to ask the Chairman why they carried forward such a largely increased balance, and whether they intended in the future to confine the dividend to its present rate for any purpose. He thought that if the liability on the shares could be reduced it would be a benefit to them and would strengthen the value of their property on the market. He thought they might regard their position as much better than it had been, and in his opinion their shares ought to stand at a much higher price.

The CHAIRMAN: I do not say what we may do in the future, but we had this legal action on, and we did not know whether we should gain or lose it. We therefore felt bound to provide for the extra expenses in case of our losing it. This, perhaps, has something to do with the amount carried forward being rather larger than it might have been. He then moved the adoption of the report and accounts.

Mr. HENRY GREWING seconded the motion, which was unanimously adopted.

Mr. B. ST. JOHN ACKERS proposed the re-election of Mr. G. B. Frost as a Director.

Mr. GREWING seconded the resolution, which was unanimously carried.

Mr. THOMAS LLOYD proposed the re-election of Mr. B. St. John Ackers as a Director.

Mr. FROST seconded the motion, which was unanimously adopted.

Mr. BENNETT PELL proposed, and Mr. CUFF seconded, the re-appointment of Messrs. Deloitte, Dever, Griffiths and Co., as auditors, which was carried.

A vote of thanks to the Chairman, Directors, and Staff terminated the proceedings.

Brush Electrical Engineering Company (Limited).

The fourth annual general meeting of this Company was held yesterday (Thursday) at the Cannon-street Hotel, E.C., under the presidency of Mr. J. B. Braithwaite, jun.

The SECRETARY (Mr. B. Broadhurst) having read the notice calling the meeting,

The CHAIRMAN referred with great regret to the loss which the Company had sustained by the death of the late Duke of Marlborough, the former Chairman of the Company. Most of the shareholders were aware of the deep and practical interest which his Grace took in every development of electrical engineering, in regard to which he spared himself neither time, trouble, nor money. He thought that, in common with the whole electrical industry, they had sustained a great loss by his removal from them. Their former manager, Mr. Garcke, had left them to join the fortunes of the Electric Construction Corporation, and they all wished him a very successful future. Mr. Garcke's place had been filled, subject to the shareholders' confirmation, by Mr. Arthur Ayres. Passing to the balance-sheet, he stated that during the past year they had issued a certain amount of additional capital, as was foreshadowed at their previous meeting. The increase of their business had been so consistent and so steady that they had found it necessary again to enlarge the capacity of their works at Loughborough; and the works manager was now crying out for more accommodation, owing to the increase in their orders. They were careful, however, not to make extensions in order to meet any sudden rush of business, but only if they had reason to believe that it would be advisable, in view of future requirements, to do so. They had expended in the year £10,681 on capital account, in additions to plant and buildings at Loughborough. They had issued 15,000 Six per Cent. Preference shares, and 11,617 Ordinary shares. They had obtained a premium on the new issue of shares and debentures of £3,150—a solid testimony to the standing of their Company and the view taken of their prospects by the investing public. The debenture stock had now been raised to its full authorised amount of £125,000. In the item of creditors there was a considerable change in the present balance-sheet compared with that of last year. They now owed £41,000, whereas last year they owed £59,624 to creditors and £19,000 on bills payable. They thus owed £37,000 less than they did a year ago, while they had owing to them £119,540, or £14,000 more. The increase in the item of stock, on the credit side of the balance-sheet, all represented orders, and therefore the increase in this item from £77,900 a year ago to £91,500 was very gratifying. They proposed to write off the whole of the item of preliminary expenses. The balance of foreign and Colonial branches stood at £61,492. The great bulk of the difference of £20,000 in this item compared with the amount at which it stood a year ago was owing to the sale of their station at Temesvar. They proposed out of the available balance of £15,894 to pay a dividend on the Ordinary shares at the rate of 7 per cent. per annum, to write off the whole of the preliminary expenses—£1,575—and to carry forward £815. Passing to the profit and loss account, he stated that there was a slight decrease in the standing charges, but during the current year they anticipated that the economies effected by concentrating all their work at Loughborough would be very apparent, and they hoped to see the item of general charges, now standing at £17,427, considerably reduced. The cost of the removal to Loughborough was an exceptional item, amounting to £1,328. They were left with a balance, being net profit of £26,394. The gross profit for the year, as shown on the other side of the balance-sheet, was £49,405, not including the profits on the Austrian and Colonial branches, but only the profit on their British

Digitized by Google

business. By writing off the items of preliminary expenses and the cost of removal to Loughborough, they got rid of the only two items which blocked the way to an increase in the dividend. In spite of the paralysis of business in Australia and the drawbacks they had had to their Austrian business, they were able to show a profit of practically £50,000 on their English manufacturing operations. They stood in a very satisfactory position with respect to orders. Their shops were absolutely full, and the only question with them was whether they could take orders for delivery within the time specified. At their works in England and Austria they were employiug 1,300 men constantly. They had orders in hand at the present time which practically enabled them to see their way to full work until they met that time next year; and orders continued to come in at a satisfactory rate. Their present manufactures appeared to command the satisfaction of those who required electrical machinery, but it was, nevertheless, necessary for the Directors to keep their eyes open for fresh developments. They constantly found fresh inventions and developments, which materially modified and altered the conditions of the industry. They had completed in the most satisfactory manner the large machines they had been building for the City of London Company. It was very necessary in the case of such a Company as that to be able to meet at once emergencies caused by any sudden demand, and the machines which the Brush Company had supplied them with had enabled them to supply their customers without any hitch or difficulty. Their Mordey-Victoria was an alternating-current machine, but it was quite a mistake to suppose that they could only supply alternating-current machines. They claimed to be able to supply continuous-current machines quite as well as any other manufacturers. They had made a satisfactory arrangement with the Otis Elevator Company for the manufacture of the elevators required by them in this country, and they could carry on this work admirably. With regard to their foreign business in Australia the complete financial collapse which had taken place there had brought business in the past year almost to a standstill, but it was very gratifying to him to be able to state that their Company had not been a loser through any of the banks which had failed in the Colony. Their business was intact, and now that affairs were beginning to resume their normal condition, they were again receiving remittances from the Colony. In Austria their profits had suffered a large diminution owing to the immense competition in the glow-lamp business; but they had made arrangements by which they would do far more work in that country, while the glow lamps would not be so important an item to them there that it had been in the past. Practically, up to this time in this country little or nothing had been done in the way of electric traction, but it seemed as if some progress was now about to be made in this direction. They were themselves exceedingly favourably situated in regard to this class of business, for they were not only able to build engines and motors, but also the cars themselves at their Falcon works. He had no doubt that when electric traction came to take a prominent place in electrical industry in this country their Company would get its fair share of the work. With regard to electricity supply stations, a great deal of progress had been made in this country. Electric lighting powers had been secured by 108 municipalities. Of these 28 had applied for authority to borrow money to carry out their powers, and 17 of them had received permission to borrow money. As far as the business of central stations was concerned, the Brush Company were getting their fair share of the work. With respect to general business, it was not necessary for him to go into details. As he had said, 108 municipalities had secured electric lighting powers, but only 17 of them had, so far, received permission from the Board of Trade to carry them out. A considerable number, therefore, had yet to come on. In London the growth of electrical supply in the past two years had been very great. At the end of 1891 the various companies in London had about 300,000 8 c.p. lamps connected to their mains, whilst at the end of 1892 they had about 500,000. It was impossible to say what the number was at present, but they knew that it was well over 500,000 and on to 600,000. The subscribed capital of the companies supplying electricity in the Metropolis was about £3,500,000. These figures showed that the electric lighting industry had emerged from the experimental stage. The number of customers connected to the mains had increased by 60 or 70 per cent., showing that the public were satisfied with the advantages of the light. The City of London Company, with which the Brush Company was more immediately connected, was receiving applications for about 1,000 lamps a week without any canvassing whatever. When they considered that every 8 c.p. lamp displaced an ordinary 5ft. gas burner, one would think that this would mean a falling-off in the gas consumption; but according to what the Chairman of the Gas Light and Coke Company said at the late meeting of that Company, the shareholders in electric lighting companies would now be able to receive their dividends without any fear that they were injuring the gas industry. Col. Makins had discovered that the falling off in the gas consumption was due to temperature, and not to electricity! The expiration of the Edison master glow-lamp patent on November 10th next would probably give an additional impetus to central-station development. The price of the lamp had hitherto been a bar to the progress of the electric light, but with the expiration of the patent mentioned the price would come down to about 1s. 6d.—a reduction which could not but incline many people to adopt the light. After November 10th this Company would be able again to supply the consumer fully—with engines, dynamos, switches, all sorts of fittings, and the lamp as well; and their arragements were complete for the manufacture of glow lamps on a large scale as soon as the Edison patent expired. He concluded by moving the adoption of the report and accounts.

Mr. B. H. VAN TROMP seconded the motion.

A brief discussion followed, and in answer to questions,

The CHAIRMAN stated that they had been running a station at Temesvar for some years, supplying electricity to the town and the public streets with the light. It was not very easy, however, to carry on such a business, and they were not sorry when the town expressed a desire to buy the works, which they had sold for what they considered a fair and satisfactory price. The whole of this money had been received. They did not think it would be to the interest of the Company to divide the item of property, patents, and goodwill. It was not the case that they were paying a dividend by means of the premium obtained on the issue of shares, but he had thought it a wise proceeding to use the money thus obtained for writing off the two items of balance of preliminary expenses and the cost of removal to Loughborough.

The motion was unanimously adopted, and resolutions were afterwards passed declaring the dividends recommended, confirming the election as a Director of Mr. Arthur Ayres, and re-electing the retiring Directors and auditors.

A vote of thanks to the Chairman, Directors, and staff terminated the proceedings.

Direct Spanish Telegraph Company (Limited).

The following is the report of the Directors of this Company for the half-year ended June 30th last, to be presented at the general meeting of shareholders to be held on Friday, September 1st, at Winchester House, E.C., at 12 o'clock:—

The accounts show, after providing for debenture interest, a balance to the credit of profit and loss of £4,645. 13s. 9d. The traffic receipts show a decrease of £593. 8s. 9d. as compared with the corresponding period of 1892. This falling off in the receipts is chiefly due to the stagnation of Stock Exchange business in England, Spain, and France. The working expenses are £130. 6s. 5d. in excess of those for the corresponding period of last year.

The Company's cables, and the land lines in connection with them, have continued in good working order throughout the half-year.

The Directors report, with extreme regret, the death of Sir James Anderson, who had been Chairman of the Board since 1884. At the invitation of the Directors, Sir John Pender, G.C.M.G., M.P., has joined the Board to fill up the vacancy. The Directors also have to report the death of Mr. Herbert R. Duke, the auditor of the Company. They have, in consequence, requested Messrs. Deloitte, Dever, Griffiths and Co. to audit the appended accounts, and an extraordinary general meeting has been convened after the ordinary general meeting to elect an auditor.

After adding the usual sum of £2,500 to the reserve fund, the balance of profit and loss amounts to £2,145. 13s. 9d. To this the Directors propose to add £345. 0s. 10d. from interest on investments, and recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference shares, and a dividend at the rate of 4 per cent. per annum (free of income-tax) on the Ordinary shares. The reserve fund will then amount to £35,963. 11s. 3d.

NEW COMPANIES, STATUTORY RETURNS, &c.

[*In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1893, pages 320-348, *&c., &c.*]

S. P. CATTERSON AND SONS (LIMITED).—This Company was registered on August 17th, with a capital of £25,000, in £10 shares, to carry on the business of lamp manufacturers, iron, brass, and metal founders and workers, mechanical and electrical engineers, manufacturers of any description of machinery, &c.

EUROPE AND AZORES TELEGRAPH COMPANY (LIMITED).—This Company was registered on August 19th, with a capital of £200,000, in £10 shares, to purchase, acquire, or construct, or cause to be manufactured, wires and cables of all kinds for the purpose of telegraphs and telephones; to acquire, by purchase or otherwise, a concession, dated June 17, 1893, and granted by the Government of His Majesty the King of Portugal to the Telegraph Construction and Maintenance Company (Limited) for the establishment of a submarine telegraph cable between Portugal and the Azores Islands, and for the laying of like cables between certain of those islands; to work the same; and to construct, maintain, and work telegraphs, telephones, and electric light works. The subscribers are:—Sir John Pender, G.C.M.G., M.P., the Most Hon. the Marquis of Tweeddale, T. Fuller, Sir A. J. Leppoc Cappel, K.C.I.E., J. Denison Pender, Admiral Sir G. H. Richards, K.C.B., F.R.S., and W. Shuter, with one share each. The number of Directors is not to be less than three nor more than five. The first are Sir John Pender, the Marquis of Tweeddale, Thomas Fuller, and J. Denison Pender. Qualification, £500. Remuneration, as fixed by the shareholders in general meeting.

MARINE SIGNALS (BARKER'S) SYNDICATE (LIMITED).—This Company was registered on August 18, 1893, with a capital of £6,000, in 5s. shares, to acquire and turn to account patents and inventions relating to marine signalling.

WATERHOUSE ELECTRO-METRIC SYNDICATE (LIMITED).—This Company has been registered with a capital of £20,000, in £10 shares, to ratify and execute an agreement which has already been prepared, and is expressed to be made between Addison G. Waterhouse and A. T. Salisbury Jones, and John J. Dale (acting on behalf of the Company) for the purchase

Digitized by Google

by the Company of certain letters patent, patent rights, inventions, &c., and to develop and turn to account the same. The subscribers are:—A. T. Salisbury Jones, H. P. Amholz, J. J. Dale, A. G. Waterhouse, F. W. Salisbury Jones, P. B. Mills, and G. Bidwell, with one share each. The first Directors are subject to the decision of the subscribers.

AFRICAN DIRECT TELEGRAPH COMPANY (LIMITED).—The annual return of this Company, made up to July 26, 1893, was filed on July 31st following, with a nominal capital of £300,000, in £10 shares. 23,600 shares have been taken up, and the full amount called and paid.

AKESTER ELECTRO-MOTOR AND ACCUMULATOR COMPANY (LIMITED). The annual return for 1892, made up to March 25th of that year, was filed in May last. The nominal capital of £5,000, in £1 shares, had all been taken up, and 3,500 of the shares were considered as fully paid. In consequence of the £1 call on the remainder, £1,153. 8s. had been paid, and £346. 12s. not yet received. Since the filing of the above and the return for 1893, 652 shares, on which £475. 12s. had been paid, were forfeited, so that only 4,348 shares are held at present. The calls paid amount to £1,324. 12s., the arrears being £175. 8s.

LINEFF ELECTRIC TRACTION AND LIGHTING SYNDICATE (LIMITED).—In accordance with a special resolution passed June 20, 1893, and confirmed July 10th following, the nominal capital of this Company has been increased from £10,000, in £1 shares, to £15,000, by the creation of 5,000 new shares of the value of £1 each.

SINGLE-WIRE MULTIPLE TELEPHONE SIGNAL COMPANY (LIMITED).—The annual return of this Company, made up to and filed on August 3, 1893, shows that 254 shares, out of a capital of £5,000, in £10 shares, have been taken up, the full amount called, and £2,540 paid.

STOKE-ON-TRENT ELECTRICITY SUPPLY COMPANY (LIMITED).—An application has been made to have this Company struck off the register.

SWINBURNE AND CO. (LIMITED).—The statutory return of this Company, made up to June 29th, has been filed. The nominal capital is £25,000, divided into 300 Deferred and 4,700 Ordinary shares of £5 each. All the Deferred and 1,686 Ordinary shares have been taken up, 200 Deferred have been issued as fully paid, while upon 660 of the Ordinary shares £2. 10s. has been considered as paid. The full amount has been called on the remaining Deferred shares, £3 per share has been called on 1,026 shares, while a call of 10s. per share has been made on the 660 (£2. 10s. paid) Ordinary shares. The calls paid amount to £3,908.

SYNDICATE OF ELECTRICAL ENGINEERS (LIMITED).—The annual return of this Company made up to July 2, 1892, was filed on June 24, 1893. The Company has a nominal capital of £10,000, in £5 shares, of which 1,081 have been taken up; 74 Founders' shares have been issued as fully paid, while a call of £4 per share has been made on the 1,007 Ordinary shares, resulting in the payment of £3,203. 10s., and leaving £824. 10s. in arrears. The usual return for 1893 made up to March 3, 1893, was filed with the foregoing. No alterations have taken place, except that the payments made have increased to £3,753. 10s., and those due proportionately decreased to £274. 10s.

TELEGRAPH MANUFACTURING COMPANY (LIMITED).—The annual return of this Company, made up to June 30th, has been filed. Although the nominal capital amounts to £50,000, in £10 shares, only 2,800 shares have been taken up, of which 646 have been issued as fully paid. The full amounts have been called and paid on the remaining 2,154 shares.

THEATRE ELECTRICAL AND SPECIALITIES PRODUCTION COMPANY (LIMITED).—The authorities have decided to dissolve this Company unless necessary returns are filed in a few days.

THETFORD ELECTRIC LIGHT AND POWER COMPANY (LIMITED).—The annual return of this Company made up to September 30, 1892, was filed on July 3, 1893. The nominal capital is £5,000, in £10 shares, of which 368 have been taken up. On these a call of £8 per share has been made, resulting in the payment of £2,921, out of a total of £2,944, while a sum of £50 has been paid in advance of calls.

UNITED RIVER PLATE TELEPHONE COMPANY (LIMITED).—The annual return of this Company, made up to July 18th, has been filed. Out of its nominal capital of £500,000, in shares of £5 each, 58,000 shares have been taken up and 16,000 issued as fully paid. The full amount has been called and paid on the remaining 42,000 shares.

WALSALL ELECTRICAL COMPANY (LIMITED).—When the statutory return of this Company was filed recently, 683 shares out of a nominal capital of £10,000, in £10 shares, were taken up; 200 of these were issued as fully paid, and the full amount has been called on the remainder, resulting in the payment of £4,780.

WEST COAST OF AMERICA TELEGRAPH COMPANY (LIMITED).—The recently-filed returns of this Company states that the whole nominal capital of £300,000, in £10 shares, have been taken up and fully paid.

WESTERN COUNTIES ELECTRIC LIGHT AND POWER SYNDICATE (LIMITED).—The first annual return of this Company, made up to August 9, 1893, shows that 205 shares of £50 each, out of a nominal capital of £25,000, have been taken taken up. Of these 120 have been issued as fully paid, while the full amounts have been called, and £4,250 has been paid on the remaining 85 shares.

WINDSOR AND ETON ELECTRIC LIGHT COMPANY (LIMITED).—The annual return of this Company, made up to August 7, 1893, was filed on the following day. The nominal capital is £30,000, divided into 5,950 Ordinary shares of £5 each, and 250 Founders' shares of £1 each. 438 £5 and 102 £1 shares have been taken up, the full amount called, and with the exception of £55 the whole has been paid. A notice was filed on August 14th that at special meetings held on July 24th and August 10th it was resolved that the Company could not continue its business on account of its liabilities, and therefore Mr. W. Sevenoakes was appointed liquidator for the winding up of the Company.

WYNNE'S ELECTRIC CLOSED-TUBE TRAMWAYS (LIMITED).—The annua return of this Company, made up to July 1, 1893, has been filed. The nominal capital is £6,000, in £100 shares, of which 54 have been taken up, 32 have been issued as fully paid, while the full amount has been called on the remainder, resulting in the payment of £2,130, and leaving £70 in arrears.

CITY NOTES, &c.

BABCOCK AND WILCOX (LIMITED).—The Directors of this Company have decided to recommend, subject to audit, dividends for the half-year ended June 30th last, at the rate of 6 per cent. per annum on the Preference shares, and 10 per cent. per annum on the Ordinary shares.

BIRMINGHAM CENTRAL TRAMWAYS COMPANY (LIMITED).—At the annual meeting of the shareholders of this Company, held on Wednesday last week at Birmingham (Mr. J. Ebbsmith in the chair), the report and statement of accounts, an abstract of which appeared in *The Electrician* for August 11th, were adopted. Resolutions were passed for the payment of a 5 per cent. dividend on the Guaranteed shares, and 2½ per cent. on the Ordinary stock.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended August 20th were £860, as against £724 for the corresponding period of last year, being a increase of £136. The total receipts for the half-year amount to £5,911, against £5,385 in the corresponding period of 1892, being an increase of £526.

CROYDON TRAMWAYS COMPANY (LIMITED).—In the course of his remarks, at the meeting of the shareholders of this Company on Tuesday, Mr. J. Carruthers-Wain said there was an item in the accounts in previous years relating to electric traction which did not figure in the present accounts. The Electric Traction Syndicate had not been able to renew its running on the Croydon line, or to make any definite arrangement. The Company was therefore without the traffic receipts for this particular form of traction, which, being a novelty, materially assisted the traffic receipts. Some new gas motors had been received for trial, which were being run at the expense of the owning companies. As these experiments cost the Croydon Company nothing they could not do better than facilitate the development of some economical form of traction, which would some day take the place of horses and be the means of saving expense to tramway companies. The arrangement made in regard to these experiments was practically on the basis of sharing profits, the Croydon Company taking no risk.

LEIPZIG TRAMWAYS COMPANY.—Mr. W. Bailey Hawkins, at the meeting of this Company on Tuesday last, said that there was one special fact to which he wished to allude, and that was that unfortunately there had been a considerable agitation in Leipzig recently with regard to the use of electricity as a motive power. He could not give the shareholders any further information on the subject, as he had nothing to form a judgment upon. In reply to a question, the Chairman further stated that the Company had not only no power to use electricity, but it was also a very grave question whether the Municipality would give them the necessary power.

LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).—This Company announces that the half yearly coupons, which fall due on September 1st next, of the £100,000 Six per cent. Debentures of the Company will be paid on and after that date by Messrs. Glyn, Mills, Currie and Co., 67, Lombard-street, E.C.

MONTREAL STREET RAILWAY COMPANY (LIMITED).—The subscription list closes to-day (Friday) for an issue of £140,000 sterling Four and a-Half per Cent. Debentures of £100 each (redeemable in 1922) in the above Company. The price of issue is £98. 10s. per cent., payable £5 on application, £43. 10s. on allotment, and £50 on September 13th next. Subscriptions are invited by the Bank of Montreal, 22, Abchurch-lane, E.C. The debentures (the prospectus states) are secured on the whole of the property of the Montreal Street Railway Company, and rank with the £60,000 Five per Cent. Mortgage Bonds issued in 1888. Interest is payable in London in February and August in each year, a full half-year's interest being due on February 1st next. The proceeds of the present issue are required for doubling the existing lines, for extensions, and for the necessary outlay for working the whole system by electricity. The Company was organised in 1860, and has a capital of $2,000,000 fully paid up. Dividends paid by the Company for the past 10 years average from 7 to 14 per cent.; for the three last years 8 per cent. has been paid.

TELEGRAPH COMPANIES' EARNINGS IN 1892.—*The Statist* of the 19th inst. contains a carefully-written article on the subject of the results of the Telegraph Companies' Earnings, &c., for 1892, which includes some figures of interest to our readers.

WEST AFRICAN TELEGRAPH COMPANY (LIMITED).—This Company give notice that the half-yearly interest, due on September 1st next, will be paid on and after that date by the National Bank of Scotland, 37, Nicholas-lane, E.C. Coupons must be left three clear days for examination.

Digitized by Google

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended August 18, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £2,386.

WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED).—The receipts of this Company for the two weeks ended August 15 were £1,855, as compared with £1,980 for the corresponding period last year. The April receipts, estimated at £6,413, realised £6,441.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 798.—Vol. XXXI. FRIDAY, SEPTEMBER 1, 1893. PRICE FOURPENCE. *Annual Subscription (U.K.), 19/6*

NOTES.

It is pretty evident from the action taken by the Municipal Corporations Association and the Glasgow Town Council, and from the frequent questioning of the Postmaster-General in the House of Commons, that the public is not disposed to allow the National Telephone Company to make too good a bargain with the Post Office. Although this cross-fire of questions has not induced the Postmaster-General to recede from the position taken up by him from the beginning, which is that he is empowered by a previous resolution of the House to settle the details of the agreement with the National Company without further ado, it has, at any rate, elicited a satisfactory assurance that when the telephone trunk wires come under the control of the Post Office no preference will be given to the messages of particular individuals. It is difficult to imagine what other answer could have been given, nevertheless the Glasgow Town Council seem to have anticipated something quite different. We trust their other fears will prove as unfounded.

The National Telephone Company, it is said, have "so negotiated the agreement that it will be found that Corporations will be placed at a vast disadvantage, and that the agreement will virtually confer on the National Company a monopoly of telephone exchange work in the country." How the Post Office, even if it desired to do so in view of future purchase of the entire system, could make the telephone monopoly more complete than it is at the present moment, by virtue of the existing Company's enterprise and the very nature of the business, we fail to see; indeed, we should have thought that with the National Company deprived of the exclusive use of the trunk wires, municipal telephony, if it is allowed, had as good a chance as it is ever likely to have.

As to the permission given to the Postmaster-General by the Telegraph Act of last year, to confer on a licencee some of the powers obtained under the Telegraph Acts, 1863 to 1889, the exercise of these powers, it must be remembered, is always to be subject to the consent of the Local Authority concerned. The reply of the Postmaster-General to the recent application of the Glasgow Town Council for a telephone licence, which will be found in our Notes columns, hints, indeed, at the grant of statutory powers to go underground. Such a grant, however, would have to be made by Act of Parliament, and if statutory powers are conferred by Parliament upon a private concern like the National Telephone Company, there need be no fear that they will be granted without some substantial concession being made to the demands of the telephoning public. That the Post Office will pay an excessive price for the trunk lines is unlikely, in view of the experience it now has of such transactions. On the other hand, no harm will be done in the long run to the public interest by paying a fair price for that which, after all, is to the Company itself a valuable adjunct to its exchange system.

The data supplied by Mr. Llewellyn Preece with regard to the placing of arc lamps, which our readers will find in another column, should prove useful to all who have to arrange for the lighting of large open spaces by means of arcs; and the series of curves which accompanies the article can be utilised to give a considerable amount of practical information regarding the character of the illumination produced by a number of arc lamps when arranged in any given manner. It may be interesting to draw attention, more fully than Mr. Ll. Preece has done, to the way in which his curves can be used. In one instance he mentions lamps placed 15ft. above the ground and at distances of 80ft. from each other. Referring to the curve for lamps placed 15ft. high we find the maximum illumination to be 1·18 candle feet, while at 40ft. from the lamp, or half-way between successive lamps, it is only 0·07 candle feet due to each arc, or 0·14 candle feet in all. The maximum illumination in this case is thus just eight times the minimum. Similarly, we find that when the lamps are 120ft. apart, the maximum illumination is 28 times the minimum, when 100ft. apart 14 times, and when 60ft. apart only three times. We deduce from Mr. Ll. Preece's numbers that on railway platforms, variations in illumination of 1 to 8 are allowable if the platforms are clear, but otherwise, to avoid heavy shadows, the change must not exceed 1 to 5, and in the neighbourhood of cranes or such structures, the variation does not exceed 1 to 2 or 1 to 3. Over the rails and cartways the change can be as much as 1 to 14, and on ordinary sidings, where little light is needed, the ratio may exceed 30 to 1.

The difficulty in measuring the diameter of a glow lamp filament by means of an ordinary micrometer, which is referred to by Mr. Ram this week, is one which also arises in micrometer measurements of the diameters of wires or sheets of very soft materials. For very exact work the arrangement

Digitized by Google

of an electrical contact answers the purpose very well. A special form of micrometer, constructed to close the circuit of a small battery and high resistance detector when the micrometer screw makes contact with the filament, is one which we have always found to give uniformly good results. It has the advantage over the method of moving the filament to and fro, that it does not strain the filament, and the current is too minute to produce any serious heating effect. The optical method described by Mr. RAM is, when properly carried out, most convenient and expeditious. It is particularly useful for measuring the diameter of a small hole in a sheet of metal, and in any laboratory or workshop in which such measurements are necessary, it would be worth while to fit up a lamp, lens, and scale in a dark corner. When the adjustments have been made once and for all, the operation of measuring would be very simple. In the *Philosophical Magazine* for the present month Profs. DEWAR and FLEMING describe the use of a microscope for measuring the diameters of wires by optical projection.

THE Paper by Mr. FREDERICK E. BEACH on the use of cupric nitrate in the voltameter, which we print elsewhere, is worthy of comment, because it marks an advance in the method of accurate electrolytic measurement on the lines which have been laid down in *The Electrician* on former occasions. Recognition of the fact that the chemical, as distinct from the electrical, attack of the electrodes is promoted by the presence of atmospheric oxygen, has led Mr. BEACH to free his electrolyte from air by boiling, and to expose it subsequently as little as possible. The practical difficulty of working *in vacuo*, and the fact that nitrogen is not a commercial commodity like oxygen, make the device of a voltameter complete in itself, and free from the air-error—no easy task. It is worth trying whether an atmosphere of CO_2 that could be obtained from a cylinder of the gas or a common Kipp would not answer the same purpose. The purity of the cupric nitrate used is another point that might have been taken direct from our own remarks on the subject. It is unfortunate that it is less easy to obtain a pure neutral solution of the nitrate than of the sulphate, but the possibility of using a high-current density outweighs this disadvantage, which, after all, is only one to put the experimenter on his mettle, and afford, perchance, a secondary and feebler stimulus to the dealer in chemicals.

THE use of ammonium chloride in Mr. BEACH's experiments is not quite obvious. Generally speaking, mixtures of chlorides and nitrates are undesirable electrotyes on account of the mutual decomposition of the salts as soon as their respective acids are liberated. The need for neutrality is therefore the greater. Moreover, any cupric chloride formed by double decomposition would act as a solvent for the copper on its own account, with the formation of cuprous chloride. No similar effect is to be expected with pure nitrate or sulphate as the existence of cuprous nitrate and sulphate is doubtful, and in any case their stability is small. The comparison of the results of the electrolysis of copper solutions with those obtained by other methods of determining the atomic weight of copper is of value, and it is gratifying to find that the latest figures—those of Prof. RICHARDS and Mr. BEACH—show a very fair concordance, and once more confirm the value Cu = 63 when O = 16.

Now and again we hear of the efforts of some inventor to produce a continuous current, such as may be used for charging storage cells, from a simple periodic current. Various rectifying commutators have been tried, but these can only produce a humpy sort of current, the sole merit of which is that it is always in one direction; a current which must be clipped up into useful and useless portions before storage cells can be charged by it. FOURIER's theorem, the refuge and strong tower of alternate-current mathematicians, tells us, of course, that a certain combination of simple periodic currents *will* give an absolutely steady current; but theoretically, at any rate, the desired result can be obtained in a much simpler manner. All that is necessary is to be able to produce a current which shall vary as the *square* of the sine of the time, instead of, as now, as the first power. Two such currents having equal periods, but superposed in quadrature, would give a perfectly steady current such as would make a battery man's mouth water. When we were at school we were taught that the sum of the squares of the sine and cosine of an angle was constant and equal to unity. Is there no one who can invent a transformer which will utilise this simple trigonometrical fact?

Durham College of Science.—The next session of this College commences on the 25th inst. Complete courses of instruction are provided in mechanical, marine, and electrical engineering, and in naval architecture.

Cable Interruptions and Repairs.—

	Dates of Interruptions.	Date of Repair.
Falmouth—Bilbao	August 17th	August 25th.
Aden—Zanzibar	August 9th	—

Type-setting by Electricity.—For some time past the larger type in the *Electrical World* of New York has been set up by machines run by electromotors. The experience in this line has been so satisfactory that in future the smaller type will also be so set up.

Electrical Bills in Parliament.—The Royal assent was given last week to the following Bills:—London County Council (Subways); Barry Railway; City and South London Railway; Hampstead, St. Pancras, and Charing-cross Railway; Blackpool, St. Anne's, and Lytham Tramways; and Dublin Southern District Tramways.

Douglas-Laxey Electric Tramway.—On Saturday last some trials were carried out in connection with this line. The experiments were carried on under the superintendence of Dr. Edward Hopkinson. All the lines have been laid, and are almost ready for traffic, but it is not expected that much will be done this summer owing to the advanced state of the season.

Electricity in Mining.—In a Paper read by Mr. F. O. Blackwell before the Mining Engineering Sections of the International Engineering Congress, at Chicago, it was stated that there were some 300 companies in the United States engaged in mining and the kindred arts that employed electricity in their operations. Nearly all of the plants were supplied with current at 220 or 500 volts, but there were a number in which voltages of 1,000 and over were employed.

Lightning.—Dr. Mitchinson, the Lincoln District County Coroner, held an inquest last week on the body of John Tinker, a labourer in the employ of Mr. Elwes, of Broxholme, near Lincoln. On Tuesday evening last week the deceased was standing on a load of corn engaged in harvest work, when he

Digitized by Google

was struck dead by lightning. The deceased's trousers and boots were cut as though by a blunt instrument, while his hat was picked up some distance away almost torn to pieces.

Transformer Patent Litigation in France.—The Orleans Court of Appeal has sustained the Zipernowsky-Déri patent, dated March 20, 1885, which claims the parallel arrangement of transformers and also the Zipernowsky-Déri-Blathy patent, dated April 21, 1885, covering the use of closed magnetic circuit non-polar transformers. The judgment of the Court of Appeal reverses that previously given by the Tribunal Civil de Tours, and is based entirely on the report made by three experts, MM. Fribourg, Jousselin, and de Parville.

Scarborough.—The Scarborough Electric Supply Company commenced the supply of electricity in Scarborough on Saturday last. The alternate-current system, with distribution from sub-stations, is employed. The charge for electricity is at the rate of 7d. per Board of Trade unit, with a cash discount and a sliding scale rebate amounting to 20 per cent. as a maximum for large consumers. The whole of the electric generating plant and transformers have been supplied by Messrs. C. A. Parsons and Co., of Heaton Works, Newcastle-on-Tyne.

Electric Launches.—Messrs. William Denny and Bros., of Dumbarton, have recently built for Capt. J. A. Allan, of the Allan Line, an electric launch from designs by Mr. G. L. Watson, of the firm of Mavor and Coulson. The launch is built to accompany the steam yacht "Hermione." Messrs. Mavor and Coulson have supplied all the electrical machinery. The total weight of the lauch is about 2 tons. The hull is built of cedar wood on the "double-skin" system. Carrying five persons, the launch attains and maintains a speed of 6½ miles per hour.

A Fence Telephone.—An innovation in telephonic communication has been adopted in Victoria. The idea consists of adapting the fencing wire running along the boundary as a means of transmitting sound. At the straining posts connections have been made, and at each gate or road a short overhead line has been erected clear of all traffic. At either end a small electric battery and transmitter is placed, thus bringing the stations, which are seven miles apart, within easy and convenient speaking distance. The cost of transforming the fence into a telephone line has been exceedingly small, and with the small annual cost of chemicals for the batteries, a complete, cheap, and serviceable connection is secured.

Charles' Law and the Gas Bills.—Our esteemed contemporary *Industries and Iron* points out that one effect of the recent hot weather must have been a considerable expansion of the coal gas supplied for gas lighting and other purposes. At a mean elevation of temperature of 10°C., a cubic foot of coal gas contains nearly 4 per cent. less mass; and, since the heating and lighting properties are proportional to the mass, it is so much the less valuable to a consumer. Vagaries of this sort are never indulged in by electricity. A Board of Trade unit never expands; in fact, after it has passed into the house, the current reaches the lamps, but a volt or two is dropped on the wires. Mathematicians should at once design a gas meter with an absolute thermodynamic compensator.

The Lauffen-Heilbronn Plant.—A note appears in the German technical papers relating to the progress of this work, a description of which appeared in our issue of January 27, 1893. The jumping of the light when motors are switched on has been overcome. When opened in January, 1892, 2,650 8-c.p. and 8-H.P. motors were on the mains; while at the end of May last the figures were: 8,180 8-c.p. lamps, and motors of an aggregate of 41 H.P.; and no less than 3,000 lamps and power for motors of an aggregate output of 20 H.P. were applied for. The price for light varies from 7½d. down to about 4½d., according to quantity consumed; while for motors the price is from 5d. down to 3d. per kilowatt hour. For instance, a ten-horse motor, used 12 hours per diem, costs about 9½d. per hour.

Dewsbury.—On Tuesday Mr. F. H. Tulloch conducted a Local Government Inquiry at the Town Hall, on the application of the Corporation to borrow £25,000 for a scheme of electric lighting. The Town Clerk said the question of supplying electric light had been under the consideration of the Council for three years, and they had come to the conclusion that such an installation was necessary in the interests of the town. They found that there was a demand for it, especially in the centre of the town. From the commencement they sought the best possible advice. They employed Mr. W. H. Preece to prepare specifications, and tenders for the works were invited, and had been let, after keen competition, and subject to the sanction of the Local Government Board to borrow the money. The Corporation did not propose to expend the whole of the money immediately. The Corporation had already spent large sums of money on the gasworks. There was no opposition to the scheme.

A Remarkable Copper Mine.—The Stora Kopparberget, Sweden, says *Industries and Iron*, is a remarkable copper mine in many ways. In the first place, it is said that it has been worked continuously for nearly 800 years, and that in the year 1228 it was yielding large profits to its fortunate proprietors. In the second place, there are actually figures extant, apparently carefully compiled, which claim to show the annual production of the mine from the year 1633, when 1,336 tons of copper were turned out, to the present time. According to these statistics, the Stora was in the heydey of its production in the middle of the seventeenth century, 3,455 tons of copper being extracted in the year 1650. Of late years, or rather centuries, the cupriferous deposits seem, however, to have become less productive. In 1750 only 782 tons were obtained; one hundred years later, in 1850, the figure was 843 tons; while in 1891 the quantity of copper produced was probably the lowest in a long record—271 tons.

The Post Office and the National Telephone Company.—In the House of Commons last week Mr. Maclure asked the Postmaster-General whether he could state when the agreement between the Post Office and the National Telephone Company was likely to be concluded and laid before the House, to which Mr. Arnold Morley replied that a draft was now under the consideration of the Company. Capt. Bagot asked the Postmaster-General whether, in the event of the Telephone Company's trunk lines being purchased by the Post Office, any and what arrangements were being made to safeguard the subscribers to exchanges of private or municipal concerns using the trunk lines from having their messages unduly delayed, or placed under any other disadvantages as compared with similar messages from the exchanges of the National Telephone Company. In reply, Mr. Morley stated that when the telephone trunk lines came under the entire control of the Post Office, their use would be subject to the usual regulations which forbade any favour or priority being given to particular persons.

Opening of the Kelvinside Electric Lighting Station.—The electric lighting station of the Kelvinside Electricity Company, Glasgow, was formally opened on Monday, at noon. Provision is made in the complete station for ten 150-H.P. boilers, and two of these are in position and under steam. The foundations for six engines and dynamos of 120 H.P. each are already in. Two engines of the Willans type are placed and are running, as are also two dynamos of the Goolden make, which work at 400 revolutions per minute. Parallel with the engine and dynamo room there is the battery room, which contains 60 E.P.S. cells capable of a maximum discharge of 1,200 amperes. Underneath the station proper there is a subway which gives access to the conductors between the dynamos and the switchboard and to the end of the feeder mains. These mains, which are of the lead-covered armoured type, are so arranged as to work on the two-wire system, to begin with. Houses are already wired for a total of some 1,500 lamps of 16 c.p. each. The works have been designed by, and carried out under the superintendence of, Mr. John M. M. Munro, of the firm of Anderson and Munro, Glasgow; and Messrs. Sharp and Kent have been the contractors for the whole work.

The "Cartesian" Ammeter.—There is no anachronism; this instrument was not invented by Descartes, but is named after the scientific toy known as the Cartesian diver, upon the pneumatic principle of which it is operated. In the toy a hollow glass vessel, more or less resembling a human figure, but

Digitized by Google

with a bulbous and highly-developed head, and with a couple of holes in its feet, is partly filled with water and immersed in a glass cylinder nearly filled with water. The top of the cylinder is covered with a stretched membrane. Normally, the diver, as the figure is called, is lighter than water; but, on pressing in the diaphragm, the air in the diver is compressed, water passes through his toe-holes and accumulates in his bulbous head, making him slowly sink. Mr. J. G. Lorrain has adapted this toy to current measurement for lecture illustration. The bulbous head is replaced by a hollow graduated stem, and a rigid air-tight plug takes the place of the elastic diaphragm. On sending a current through a resistance coil placed in the upper part of the cylinder the pressure of the air in this part increases, and water enters the graduated stem and sinks it to a point which depends on the current strength. Mr. Lorrain says there is no patent on this instrument, and that the world is welcome to it. But, unfortunately, the temperature errors are too great for the world to be likely to use the instrument where any exactitude is required.

The Queenston-Chippewa Electric Railway.—The *Electrical Engineer* of New York for August 9th contains an interesting account from the pen of Mr. T. C. Martin of the latest Canadian electric railway, that running from the head of Lake Ontario along the Niagara River to the end of Lake Erie, a distance of about 13 miles, of which no less than 37 per cent. is on curve. "The first thing that strikes an observer," says Mr. Martin, "is the British solidity and massiveness of the construction. It is regular steam railroad work and a little more." Part of the line is equipped with tubular steel poles, the rest with cedar poles. The trolly wire is No. 00 B.W.G. hard-drawn copper. The rolling-stock consists of 16 motor and 18 trail cars, the motor cars each having two 50-H.P. motors. The line passes over three heavy bridges and a trestle bridge 500ft. long and 150ft. high. The power is obtained from the Niagara River just above the falls, water being supplied under a head of 62ft. to two 1,000-H.P. Leffel turbines, which are coupled to a set of 200-H.P. four-pole generators. There is a supplementary steam-power generating station at the other end of the line containing two 100-H.P. generators. This plant is only intended to be used in the busy summer months, when excursion parties of 1,000 to 1,500 persons are constantly being landed at Queenston from the Toronto steamers, and require to be taken up the mile and a-half of 5 per cent. to 6 per cent. gradient.

American Indians and Electricity.—The modern marvels of electricity, says the *Electrical Review* of New York, have not been appreciated by the Indians who have done their best to stop their importation. A telephone line had been laid down by the Government between La Paz (Bolivia) and Lake Titicaca, 45 miles away, but the Indians got the idea that the much-sounding talk of the white man that could be heard thus far would disturb the long sleep of their ancestors, and they stole the wire and used the poles as firewood. These were replaced, but at last the whole line was ruthlessly torn down, and the Government was compelled to abandon it. The Indians next turned their attention to the electric light plant, which was being installed here, and awaited an opportunity of destroying it. After the plant had been in operation a few nights there was an eclipse of the moon. The Indians believed that the electric light was absorbing or swallowing the moon, and, gathering in a body, moved upon the plant to destroy it. It was saved only by the intervention of a large body of troops. The Government next day selected several representative Indians, took them to the power house and shocked them severely, then took them out along the line and shocked them again with the wires. After this they informed them that the electric light was an evil spirit, and that they had better leave it alone. The Indians were convinced that they could not fight against an enemy that could twist their muscles into kinks when miles away, and there has been no further trouble.

Reinforcing Steam Pipes.—It has been proposed more than once, says *Engineering*, to reinforce copper steam pipes by shrinking steel rings around them. Theory, however, shows that unless these rings are very closely spaced the pipe may actually be weakened by their presence, and the correctness of this view was borne out by a series of careful experiments made on this point by Commodore George W. Melville, chief of the Engineering Bureau of the United States Navy. Comparative tests by him between plain and reinforced pipes showed both to fail at practically the same pressure. In the Italian Navy the plan of reinforcing the pipes with wire has definitely been adopted, and is described by Mr. Nabor Soliani in the *Revista Marittima*. The practice is to serve the tubes over with one or more layers of closely laid metal wire, wound on under tension. Up to about 8in. in diameter drawn tubes are used without reinforcement. Above this diameter, however, the tubes are made out of copper sheets by brazing in the usual way, and are then wrapped round with a close spiral of copper or Delta metal wire. This method of reinforcement is only considered applicable to straight tubes, and, accordingly, these only are used, gun-metal castings being adopted at the elbows and bends. The wire is of sufficient section to carry the full steam pressure independently of the strength of the tube; the latter is, however, made strong enough to stand the usual hydraulic test before the wire is put on. The reinforcement is made up with two or three independent spirals, so that if one wire breaks the tube is still held up to its work by the others. The ends of these separate spirals are fixed independently to the flanges. The tension at which the wire is wound on is about $1\frac{1}{2}$ tons per square inch.

The Telephones at Glasgow.—The following is the reply of the Postmaster-General to the application of the Glasgow Corporation for a telephone licence:—"Sir, I am directed by the Postmaster-General to acknowledge receipt of your letter of the 12th instant, enclosing an application from the Lord Provost, Magistrates, and Council of Glasgow for a licence to establish a telephone exchange within that city. The Postmaster-General observes that the application refers to a recommendation of the recent Joint Committee on Electric Powers, and he thinks it right to inform you that he has received a communication on the subject from the Association of Municipal Corporations. The question whether measures shall be taken, and if so what measures, to give effect to this recommendation of the Joint Committee must engage the very careful consideration of Her Majesty's Government; and the Association has been informed that no final step will be taken until they have been afforded an opportunity of expressing their views. In these circumstances, and in view of the intimate relation between the question of fresh licences for telephone exchange business, and that of statutory powers for laying telephone wires underground, the Postmaster-General does not feel that he can at present arrive at any decision on the application enclosed in your letter."—The deputation of the Glasgow Town Council which came up to London in connection with the municipal telephone scheme and cognate matters, was received privately by the Postmaster-General on Wednesday last. Sir Charles Cameron, M.P., introduced the deputation, who asked that the Corporation should be allowed a licence to start a municipal telephone exchange. Mr. Provand, M.P., supported the views of the deputation. The Postmaster-General, in reply, said he would come to no decision adverse to municipal enterprise. The Government would not at all interfere with the freedom of municipal enterprise with regard to any matters it could legitimately control for the public interest. The telephone, however, was not a part of municipal business, but belonged to the telegraph system, which was conducted by the State. It was not confined to the municipal area like water, gas, or tramway works. In continuance of the policy of the late Government, he was now engaged in purchasing the trunk lines of the telephone system, and until that was completed it was impossible to consider the question raised by the present application. The movement might possibly develop into the Government's taking over their entire management, but any step taken in advance in local districts would complicate matters. He was strongly in favour of further powers being given to the municipalities to manage affairs which were strictly municipal, but he could not enter into further details on the question raised by the deputation until the agreement as to the trunk telephone lines had been finally settled.

ELECTRIC MOTIVE POWER.*

BY ALBION T. SNELL.

(*Continued from page 335.*)

Parallel Working.

The term "parallel" is applicable to a number of systems of distribution, in all of which the current is divided into branch circuits, and the energy is supplied to the distributing mains at approximately constant pressure. The conducting circuit may be complex, and as it will be necessary to make frequent reference to its various parts, it will simplify matters to define the terms used in these pages.

The feeding mains, or simply the *feeders*, are the large conductors which carry (high or low pressure) current to a central point of distribution, or to the nearest motor, in a simple parallel case. They may be long or short, according to circumstances, but since their function is that of carriers only, they relate to the transmission part of the problem, and are distinct from the distributing net work of mains. Feeders, therefore, are never tapped by branch connections.

The distributing mains, or briefly the *distributors*, are designed to carry the current from a centre of distribution, *i.e.*, the end of a feeder, to the service mains which supply each consumer. They will vary in section and length according to the area to be served, and may form simple radial lines from the distributing station, or in some cases a complicated net work looped at the extremities by ring mains. Distributors may be tapped at any point in their length to supply current to consumers.

The *Service mains* are the pairs of conductors connecting a motor or bank of motors (or lamps) to a distributor.

The parallel systems suitable for power work are :—

(*a*) Simple parallel, reverse parallel.
(*b*) Feeder system.
(*c*) Three-wire system.
(*d*) Multiple-wire feeder system with regulators.

Inspecting Figs. 26 to 34, which illustrate diagrammatically the several arrangements, it will be seen that the condition of constant pressure between the distributors is common to all, and that since the energy at any point is equal to the product ei_n, it follows that variations of load have to be made by changing the current of the particular motor (or lamps). This is exactly the converse of the series system of supply. The immediate effect of the variable current is to cause the loss in the mains (feeders and distributors) to vary with the square root of the load. This is an advantage, since the line loss is then in proportion to the useful effect; but it also causes the pressure at different parts of the line to vary inversely as the load, which is exactly the opposite of what is required.

The line loss is expressed in watts by :—
$i^2 R + i_1^2 R_1 + i^2_2 R_2 \ldots + i_n^2 R_n$, where i, i_1, $i_2 \ldots i_n$ are the several currents in different parts of the circuit, of which the respective resistances are R, R_1, $R_2 \ldots R_n$. And the fall of pressure in volts on the several sections is given by iR, $i_1 R_1$, $i_2 R_2 \ldots i_n R_n$.

The aim, then, in a parallel system will be to compensate for the drop in the feeders, and to keep the pressure constant at the centre of distribution. There will remain a slight fall of pressure uncompensated for between this centre and the points of supply, *i.e.*, the motor terminals. But this is practically unavoidable, and in most cases can be made so small as to give no trouble if sufficient copper be put into the distributors and service mains; for then the product iR becomes so small, even at full load, as to be insignificant. The weak point in simple parallel working is that the pressure is limited by the voltage of the smallest motor, or that of the lamps run in parallel with the motors. In lighting circuits, where incandescent lamps requiring about 100 volts are mainly used, the pressure at the centre of distribution is necessarily about 100 volts, although at the station it must be higher by an amount determined by the resistance of the conductors. In power circuits where lighting is of secondary importance the pressure on the distributors may be, say, from 300 to 500 volts: and lamps may be coupled in series to make up the required voltage. Thus three incandescent lamps of 100 volts each may be coupled in series across a pair of mains having a pressure between them of 300 volts; and, similarly, five 100-volt lamps may be placed across a 500-volt circuit (*see* Fig. 26).

Raising the pressure of distribution permits a reduction in the weight of the copper, but at the same time introduces complications which require careful attention.

In the first place, consider a constant length of conductor, with constant power at supply station, and let the pressure of supply be varied. As before :—

a = area of conductor.

R = resistance of conductor = $\frac{l}{a}k$, where l = the length of conductor and k is a constant.

e = pressure of distribution.

Then we have

$i^2 R$ = line loss; $\frac{i}{a}$ = the current density.

iR = drop of pressure in volts.

ei = the power transmitted = a constant.

Now assume that the pressure is doubled so that it may be represented by $2e$, then the current will be $\frac{i}{2}$, since the power is to be the same as before.

The line loss will now be $\left(\frac{i}{2}\right)^2 R = \frac{i^2 R}{4}$, *i.e.*, only one-fourth as great; and the drop of pressure will be $\frac{i}{2}R$, or one-half. The section of the conductor may, therefore, be safely reduced.

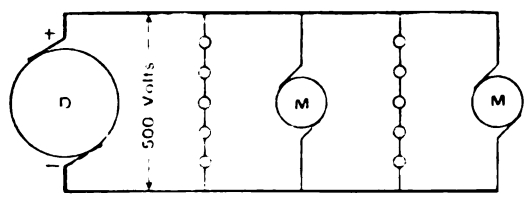

FIG. 26.

There are two cases of importance in practice.

Firstly, when it is essential to keep the *line loss*, $i^2 R$, constant. In this case the area of the new conductor need only be one-fourth of the old one, and will have four times the resistance; or the line loss will be $\left(\frac{i}{2}\right)^2 4R = i^2 R$, the same as before; and the line drop will be $\frac{i}{2}4R = 2iR$, or the same *percentage* drop as before, which is equivalent to saying that *the line loss remains constant when the percentage of the line drop is kept the same for variations of supply pressure.* It must be noticed that the current density has been doubled, for it is now equal to $\frac{i}{2} \div \frac{a}{4} = 2\frac{i}{a}$.

Secondly, when it is necessary to keep the *line drop*, iR, constant. This can be accomplished by using a conductor of half the area and twice the resistance, for then the drop $= \frac{i}{2}2R = iR$, as in the first case. And the line loss will be $\left(\frac{i}{2}\right)^2 2R = \frac{i^2 R}{2}$, or only one-half as great as before. Therefore the economic current ratio, $\frac{i}{a}$, is also constant, for both current and area of conductors are halved. Or, generally when *the current density is kept constant, the line drop is also constant for variations of supply pressure.*

The latter of these two cases is, perhaps, of the most importance in relation to the feeders, for in relation to them the economic current density is the chief consideration, and the ratio $\frac{i}{a}$ should have the same value in both long and short feeders, the different drops of pressure being compensated at the supply station. Strictly speaking, on the score of economy,

Digitized by Google

the same considerations should determine the gauges of the distributors, but frequently the fall of pressure will be the only criterion, and then the conditions suggested in the first case will obtain, viz., a constant percentage of drop.

If the current density be settled, as it should be, in accordance with the economic law, the current varies as the area of the conductor, $\left(\text{or, } \frac{i}{a}\right)$, and the drop, i R, is simply proportional to the length of the conductor. For each pressure of supply and current density, then, there will be a definite distance through which the power can be transmitted for a given drop. This distance includes the feeders, the distributors, and the service mains, if the drop be measured from the dynamo to the motor terminals; but in most cases it will be convenient to consider the three drops separately.

The fall of pressure for any section may be determined in the following manner if the current density, $\frac{i}{a}$, be fixed :—

$$i\,\mathrm{R} = i\frac{l}{a}k. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

And if l be expressed in yards and a in square inches (the most convenient and practical units for these calculations), then k will be the numerical value of the resistance of one yard of copper of one square inch in cross section, and will be approximately equal to $\frac{25{\cdot}6}{10^6}$ for ordinary commercial samples. Therefore

$$i\,\mathrm{R} = l\frac{i}{a}\cdot\frac{25{\cdot}6}{10^6}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

From this equation, if we know the drop, we can find the possible length of conductor; and if l be determined, then the corresponding drop can be estimated.

It will sometimes be more convenient to estimate the drop in terms of the length of the section (measured along the conductors) rather than in terms of the length of conductor. To do this it is only necessary to put l, equal to the length of the section, and multiply the right hand member by 2; thus

$$i\,\mathrm{R} = 2\,l_1\frac{i}{a}\frac{25{\cdot}6}{10^6}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

If $i\,\mathrm{R} = 1$, then l_1 will give the number of yards per volt drop for the particular value of the economic ratio $\frac{i}{a}$.

The following table has been prepared in order to give the reader a graphic idea of the effect on the drop for different pressures and distances, with various current densities :—

Table I.—*Two Wire Mains. Drop of 1 per cent.*

Current density in amperes per square inch.	Distance in yards from the central station for a drop of 1 per cent. at the following pressures of supply.			
	100 v.	200 v.	500 v.	1,000 v.
1,000	19·5	39·0	97·5	195·0
900	21·75	43·5	108·75	218·0
800	24·5	49·0	122·5	245·0
700	27·75	55·5	138·75	278·0
600	32·5	65·0	162·5	325·0
500	39·0	78·0	175·0	390·0
400	49·0	98·0	245·0	490·0
300	65·25	131·5	316·0	653·0

To find the distance for a drop of n per cent., multiply the distance in the columns against the given pressure and current density by n.

In the above table the percentage of drop in the line and the current density are kept constant for pressure variations, both current and area of the copper varying inversely with the pressure of supply. The line loss, $i_m{}^2$ R, will remain constant under these conditions.

(To be continued.)

The Measurement of Insulation Resistance.—A prize of 2,000fr. is offered by the Société d'Encouragement, for an apparatus or industrial process for quickly measuring the insulation resistance of the various parts of an electrical plant while in operation. The prize will be awarded in 1895.

THE PLACING OF ARC LAMPS.

BY LLEWELLYN PREECE.

Although it can hardly be said that the Midland Railway has any fixed rules with respect to the placing of arc lamps, as so much depends on the local arrangements, &c., each place to be lighted, there is a standard of illumination to which is adhered to as nearly as possible, and there are, therefore, fixed outside limits for the distances which lamps may be placed apart. A few notes on these limits may be of interest to those engaged on similar work.

Arc lighting on the Midland Railway is carried out principally in goods sheds, goods yards, and passenger stations. In goods sheds there are the platforms (or decks, as they are usually termed), the cartways, and the metal roads to be lighted. For the decks the limit is 70ft. The standard of illumination is that a man standing anywhere shall be able to read with ease an ordinary label; this is obtained with lamps at distances of 80ft. over a clear platform, but owing to the generally crowded condition of a goods shed deck, 70ft. is the maximum distance at which lamps can be placed without heavy shadows being thrown. In practice, however, it is the distance apart of the cranes—of which there are always a number—which finally determines the distance of the lamps. These cranes, which have as a rule a working radius of 16ft., are placed apart at distances varying from 40ft. to 60ft., and it is found that the best illumination and safest positions for the arc lamps is down the centre of the platform and midway between each crane and the next. Where the platforms are very broad and two rows of cranes are required, it is best to have two rows also of lamps, and as before, midway between the cranes. Over cartways and metal roads, the amount of illumination required is not so great, and the lamps may well be placed 100ft. apart, except in cases where unloading is carried on direct from the trucks to carts, when, as sufficient illumination is required for reading labels easily, 80ft. should be the limit. The distance apart of the rows of lamps depends to a great extent on the arrangement of the decks, roads, and cartways, and also on the size and distances apart of the pillars which carry the roof. 80ft. may be taken as about the average, however.

The height of the lamps above the decks has, after considerable experimenting been fixed at 14ft. If brought any lower, complaints are made that the light is too dazzling. Over the roads and cartways 18ft. is usual.

Goods yards are made up of points, sidings, unloading roads, and approach roads. For "nests" of points and unloading roads it is found that 100ft. to 110ft. give the best results, the lamps being always 20ft. in height. In the case of single points we find it best to place lamps also, as it is at such places lights are chiefly required in a yard. At the same time it is very inadvisable to leave gaps of a greater length than 250ft. between any two lamps.

With regard to the ordinary sidings, no light is required except with sidings used for marshalling trains at night, in which case the lamps may be 120ft. apart. Approach roads have lamps usually from 120ft. to 150ft. apart, this giving ample illumination. Lamps at a height of 25ft. would give the best results in this last case, but on the Midland the lights are fixed at 20ft., as this enables us to have only one size pillar.

With regard to passenger stations on main line platforms the limit is 80ft., on local platforms 90ft. The actual distances, however, depend on the spaces between the girders carrying the roof, as it is the invariable practice to hang the lamps from the girders. So that in some cases lamps are placed considerably nearer. At St. Pancras, for instance, the girders being 30ft. apart, the lamps on the main platforms are placed at distances of 60ft. In the booking halls the position and the distances of the lamps are somewhat subject to appearances, and 60ft. is about the outside limit. The height is always 14ft., the same as in goods sheds.

I have supposed throughout that we have been dealing with the 500-watt lamp, or nominal 2,000 c.p. But in several places the Company uses the 350 watt lamp—nominal 1,200 c.p., in which cases the limits are reduced by 10ft. or 15ft. Opalescent

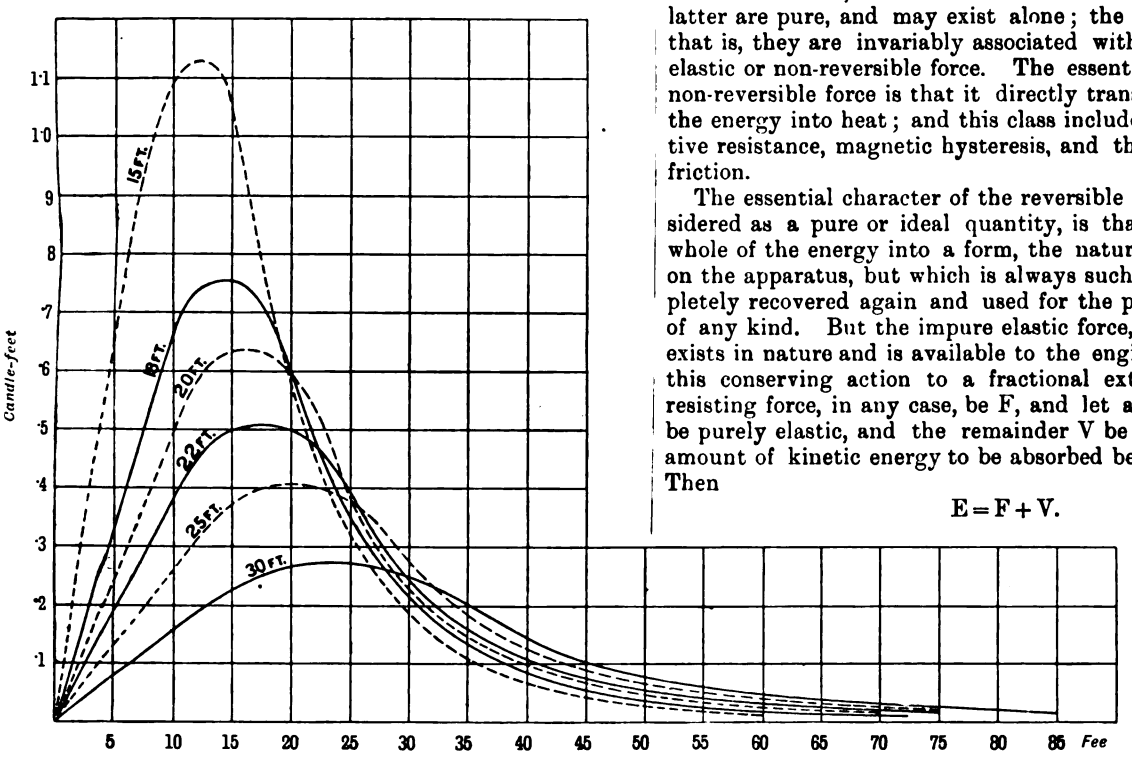
bes are used in goods sheds and passenger stations, clear bes in yards and approach roads.

The accompanying diagram is a series of curves showing the minating power of a 1,000-c.p. arc lamp at various heights. In A. P. Trotter's Paper on "The Distribution and Measurement Illumination," read before the Institution of Civil Engineers May, 1892, it is shown that the illumination of an arc lamp ries as the fourth power of the cosine of the angle of incnce ($\cos^4 \theta$) for angles greater than 45deg., and also that the umination at about this angle is at the maximum. The rves are arrived at from this information, being obtained as llows:—Assuming the light of the lamp to be 1,000 candle wer, the illumination underneath the lamp, ignoring the wer carbon, would be 1,000 candle feet divided by the uare of the height. This may be taken as the value illumination with θ at 0°. The curve, however, only starts



45deg, the value $\cos^4 \theta$ being 0·25. The actual maximum therefore 0·25 the supposed value under the lamp. Startg from this point the curves are the various values of $\cos^4\theta$ ivided into the supposed value of illumination under lamp. he ordinate is marked out in feet instead of the angles of cidence, being simpler for practical work. The scales both r the feet on the abscissa, and candle feet on the ordinate are ite arbitrary.

The practical use of this diagram is to enable designers for e arrangements (as regards height and distance apart) of arc mps to obtain some idea of the resulting illumination that ll be obtained with lamps fixed at various heights and disnces, or having been given a minimum and maximum illumiation, to so arrange their lamps that the desired result may obtained.

THE ABSORPTION OF ENERGY.

Although a supply of energy is indispensable to animate stence on this globe, and notwithstanding the care by which sources of nature are directed by engineers for the use and venience of man, there is, besides a huge waste of energy, a tinual need for dissipating it. Surplus energy is in most, if in all, cases kinetic, as the character of potential energy is h that its non-dissipation is not liable to exert prejudicial ions. Some examples of the intentional dissipation of surplus energy occur in the shading of a light of brilliance, by an obscured globe or a window blind, the use of a fire screen, of a Prony brake, a resistance coil with arc lamps in parallel, and a carriage brake. In some of these there is no attempt at conservation or diversion of the redundant energy, but in others, utilisation is possible. There are two general kinds of absorption: 1st, where the surplus energy is directly dissipated as heat; 2nd, where it is made to perform some useful work, or is stored in some efficient accumulator before being ultimately spent as heat. The energy of every mechanical contrivance finally escapes as unavailable radiation into space; and all that man can do is to hinder its dissipation and make it do some useful thing before it leaves him for ever. This is called useful work.

In general, there are two forms of resisting force which may be opposed to a quantity of kinetic energy; namely, reversible or elastic forces, and non-reversible or viscous forces. The latter are pure, and may exist alone; the former are impure, that is, they are invariably associated with an element of inelastic or non-reversible force. The essential character of the non-reversible force is that it directly transforms the whole of the energy into heat; and this class includes electrical conductive resistance, magnetic hysteresis, and the various forms of friction.

The essential character of the reversible or elastic force, considered as a pure or ideal quantity, is that it transforms the whole of the energy into a form, the nature of which depends on the apparatus, but which is always such that it may be completely recovered again and used for the performance of work of any kind. But the impure elastic force, such as that which exists in nature and is available to the engineer, only performs this conserving action to a fractional extent. Let the total resisting force, in any case, be F, and let a portion, E, of this be purely elastic, and the remainder V be viscous, and let the amount of kinetic energy to be absorbed be represented by K. Then

$$E = F + V.$$

This total energy will be absorbed in a time

$$t = \sqrt{\frac{2K}{a(F+V)}}.$$

Where a is the acceleration (negative) or the ratio of the resisting force to the reduced inertia at its point of application. Calling this latter quantity I, we get the general expression

$$t = \sqrt{\frac{2KI}{(F+V)^2}}.$$

And the distance or linear movement of the point of application of E will be

$$s = \frac{K}{F+V}.$$

During this action, represented by the above equations, the energy K has been transformed into a dissipated amount equal to Fs and a stored amount Vs, so that the efficiency of the absorption—assuming it is desired not to dissipate energy—is the ratio of the elastic to the total force. This fact is at the basis of all storage and usefully-absorptive apparatus. Among the class of practical reversible forces for absorbing energy we may include: the actions which arise in an ideal secondary battery, there being a purely elastic reaction called a chemical electromotive force, and an inelastic reaction called the internal resistance; the thermo-electric effects at the junctions of two dissimilar metals; the self-induction effect of an electromagnetic circuit; the elasticity of a coiled-up spring, or of compressed gases; and the elevation of water or other masses to a distance above any level to which they may return.

THE USE OF CUPRIC NITRATE IN THE VOLTAMETER AND THE ELECTRO-CHEMICAL EQUIVALENT OF COPPER.*

BY FREDERICK E. BEACH.

Among the voltameters in common use the silver voltameter gives results of a very high degree of accuracy, but is not conveniently used except for comparatively small currents. On the other hand, the copper voltameter from the cheapness of materials and facility of manipulation finds convenient employment in the laboratory. As ordinarily used with the sulphate of copper, it is subject to certain irregularities due to the attack of the copper by the solution under some conditions, and the oxidation of the metal in others. For these reasons as well as for the fact that excellent deposits of metal are obtained from the nitrate of copper, even with great current densities, it seemed probable that this salt could be successfully used in the voltameter. The object of this Paper is to show that cupric nitrate has some marked advantages over the sulphate. For purposes of comparison the results and conclusions of different experiments will be passed in review.

Gore† expresses the opinion that two independent forces act in the solution, one chemical the other electro-chemical. The action of the former is assisted by a rise of temperature. The loss of the anode is greater than the gain of the cathode, but the chemical corrosion of the anode is less than that of a separate piece of copper without a current. The purely chemical corrosion of the cathode is more than that of the anode. The addition of any considerable amount of sulphuric acid had the effect of diminishing the weight of copper deposited.

Hammerl‡ as the result of a detailed investigation comes to the following conclusions :—

I. No change in the quantity of the deposit was observed when a blank platinum surface was substituted for one which had been covered with a deposit of copper.

II. The change of concentration of the solution caused by the psssage of the current and the polarisation dependent on it cannot be satisfactorily prevented by agitation. In boiling to agitate the fluid the deposit oxidises almost completely to Cu O, and partially indeed between 40° and 60°C.

III. The highest allowable current strength is seven amperes per square decimeter. The distance between the plates should not be less than 1·5 cm.

Gray§ finds that the highest current-density desirable is one ampere to 50 square centimetres $\left(=0{\cdot}02\ \frac{\text{amp.}}{\text{cm.}^2}\right)$. He obtains the ratio $\frac{Cu}{2Ag}=0{\cdot}2940$, and for the electro-chemical equivalent of copper $0{\cdot}0003287\ \frac{\text{gm.}}{\text{amp. sec.}}$ when silver is taken as 0·001118. He remarks "This would indicate a value not diffesing much from 0·0003290." He does not find as did Gore, that loss by chemical action is less when the current is flowing than when it is not. Copper was dissolved in the sulphate at the rate of $0{\cdot}02\ \frac{\text{mgm.}}{\text{cm}^2.\ \text{hr.}}$. Addition of sulphuric acid seemed to retard the loss when the density of the solution was between 1·1 and 1·15.

Gray‖ using a density of the sulphate solution of 1·15 to 1·18 with one per cent free sulphuric acid found that the equivalent depended on temperature and current density in a manner which is exhibited by the following table. The factor 10^{-7} has been omitted.

Area of cathode in sq. cm. per ampere.	Temperature.				
	2°C.	12°C.	23°C.	28°C.	35°C.
50	3,288	3,287	3,286	3,286	3,282
100	3,288	3,284	3,283	3,281	3,274
150	3,287	3,281	3,280	3,278	3,267
200	3,285	3,279	3,277	3,274	3,259
250	3,283	3,278	3,275	3,268	3,252
300	3,282	3,278	3,272	3,262	3,245

Vanni¶ found that a solution of copper sulphate of density 1·12 with 1 per cent. of free sulphuric acid dissolved copper, while a solution neutralised with copper hydrate gave an excess. Combining a liter of the normal solution with a half gram of that containing 1 per cent. of the acid, neither a gain nor loss could be observed in the weight of a piece of copper immersed in it.

The mean of six experiments with such a solution showed $\frac{Cu}{2Ag}=0{\cdot}2938$, whence Cu equivalent $=0{\cdot}0003284$ with a current-density between 0·011 and 0·002.

Cintolesi† observed that the solution of a copper plate in copper sulphate depends on the time and the current strength. In vacuo the amount of copper dissolved is less than in air. Oxygen was believed to have an essential influence on the phenomenon.

Shaw* using copper sulphate, and a current density above $0{\cdot}025\ \frac{\text{amp.}}{\text{cm}^2}$, found as a mean of fifteen experiments that the ratio of $\frac{2Ag}{Cu}$ was 3·39983 or Cu equiv. $=0{\cdot}00032886$.

It thus appears that the behaviour of copper sulphate had been thoroughly studied ; but no quantitative determination had been made with the nitrate, as far as the writer knows, although it had been stated by Smee and others that the nitrate would bear a much greater current density than the sulphate.

The apparatus used in the experiments presently to be considered may be briefly described as follows :—The cathode was made from a piece of electrolytic copper, about 2mm. thick, by bending it so as to form three sides of a rectangle. This was immersed in copper nitrate contained in a glass beaker. The anode was usually a thin sheet of platinum, though copper was occasionally substituted for it. The former was much preferred on account of the ease with which the copper is removed by dipping in nitric acid. After rinsing with water the platinum electrode may be dried by heating to redness in a Bunsen flame. The current was measured by the silver voltameter when small, and Thomson balance in a few instances when the total current was large. The value of the equivalent of silver used in calculating the numbers hereafter given was 0·0011181, the mean of the value 0·0011183 found by Kohlrausch† and 0·00111794 the one given by Rayleigh.‡

It was found, early in the course of the work, that when the nitrate solution was freshly prepared it had a tendency to dissolve copper, and that this tendency, which was due to the solvent action of the solution itself or the presence of a small quantity of free acid, decreased after the copper electrode had been kept in the solution a sufficient length of time, and that this latter effect seemed to be facilitated by the passage of the current. On the other hand another difficulty to be contended with was the oxidation of the copper deposited after the solution had been used too many times or the current was pushed too far, causing in many cases a darkening, or even perceptible blackening, of the metal. It was, however, discovered that the blackening due to oxidation could be prevented by the addition of a small amount of ammonium chloride.

Experiments were now made, in which the current density was varied through a considerable range, with results which are given in the following table :—

No.	Solution.	Current-density amperes / cm²	Cu. Eq. · 10
1	$Cu(NO_3)_2$ nearly neutral without NH_4Cl	0·035	3291
2		0·065	3291
3		0·144	3293
4		0·024	3293
5		0·83	3305
6	$Cu(NO_3)_2$ with NH_4Cl	0·114	3290
7		0·074	3297
8		0·076	3298
9		0·094	3299
10		0·019	3290
11		0·048	3297

These values show no dependence on the current-density except No. 5, where the large value of the equivalent is best accounted for by oxidation caused by the excessive current. This deposit was badly fringed at the edge, and easily detached. Nos. 1—5 made by repeated use of the same solution, show more uniformity than was at any other time obtained from a solution without ammonium chloride present. Attention may be called to what appears to be evidence of the neutralisation of the solvent effect of the nitrate on the copper in the gradual but not always regular increase in the values obtained from the same solution in successive experiments.

Having now obtained a fair control of both the tendency to oxidation and solution, experiments were next undertaken with a view to determining the value of the electro-chemical equivalent. With the exception of Nos. 1—5 already quoted, the solutions used in obtaining the numbers given in the First Series were alike in that they were neutral with respect to the copper, and contained NH_4Cl.

No.	First series. Equivalent × 10^7.	No.	Second series. Equivalent × 10^7.
1	3291	33	3294
2	3291	34	3296
3	3293	35	3290
4	3293	36	3293
5	[3305]	37	3295
12	3296	38	3294
13	3297	39	3296
14	[3305]	40	3298
15	3293	41	3293
16	3294	42	3291
17	3296	43	3292
18	3294	44	3302
19	3292	45	3296
20	3300	46	3293
21	3299	47	3294
22	3299	48	3291
23	3291	49	3292
24	3295	50	3293
25	3294	51	3292
26	3292	52	3293
27	3300	53	3292
28	3292	54	3291
29	3296	55	3298
30	3301		
31	3291		
32	3295		

The mean of the First Series, including Nos. 5 and 14, is $3295{\cdot}6 \pm 0{\cdot}54$. If these experiments be excluded we get $3294{\cdot}8 \pm 0{\cdot}43$.

Neutralisation of the solution in the experiments described had been effected by repeated use. A readier method which suggested itself was to boil the nitrate in order to expel the air, allowing a piece of clean copper to stand in the hot solution until its solvent action had been exhausted. Such solutions were prepared and after the addition of a small amount of NH_4Cl yielded values tabulated in the Second Series, the mean of which is $3293{\cdot}9 \pm 0{\cdot}4$.

In some cases the solutions employed were used many times so that the tests to which the nitrate has been subjected are in this respect particularly severe. There is good reason for supposing that the numbers would have been more consistent if a fresh solution had been used each time.

It is natural to inquire how the values found agree with the equivalent calculated from the atomic weight of copper.

The last-named quantity has been investigated with great care by T. W. Richards* with the following result :—

If silver be taken as 108·00, oxygen as 16·000 and bromine 80·007.

From Cu : 2Ag he finds Cu = 63·640
Cu : (2AgBr) Cu = 63·648
$CuBr_2$: 2Ag Cu = 63·643

Cu = 63·644

whence we get $\frac{Cu}{2Ag} = 0{\cdot}29465$

and Cu Equivalent = 0·00032944
when silver is taken = 0·0011181.

Hence the value here found is substantially in accord with Richards'. In making this comparison it must be borne in mind that the present investigation was not undertaken for the purpose of finding the equivalent of copper but to determine how well the nitrate would serve as the electrolyte in the copper voltameter, and that, too, throughout a considerable range of conditions. That these conditions when working with such a sensitive metal as copper were sometimes unfavourable to uniformity of result may be sufficient to explain the amount of variation from the mean. The probable error of a single observation in the Second Series is $\pm 1{\cdot}9$.

Further experiments were tried to determine the effect of variations in the temperature. Here again it is to be remembered that the solutions were not freshly prepared. A considerable change of temperature either up or down seemed to favour oxidation, but more particularly the latter, probably on account of the increase in concentration of the salt when cooled. Still even this was in great measure prevented by a sufficient addition of the ammonium chloride.

No.	Solution.	Temperature.	Equivalent × 10^7.
56	$Cu(NO_3)_2$ with NH_4Cl	19°	3296
57	Same.	6	3297
58	Same.	34	3292
59	Same.	29	3321
60	Another solution.	18	3291
61	Same.	36	3297
62	Same.	37	3296
63	Same.	6	3313
64	Same.	10	3307
65	A different solution.	40	3291
66	Same.	10	3292

From these experiments we may conclude that a moderate change of temperature is not a critical matter.

The First and Second Series were made at the temperature of the room which did not vary much from 19°C.

The following method is recommended for the preparation of the solution : Dissolve copper nitrate, the purest obtainable, in distilled water. Boil for a short time to expel the air and keep at a temperature of 100°C. for an hour or two in the presence of bright metallic copper in order to completely neutralise the solution. When ready for use it should have a density of about 1·53. Add a saturated solution of NH_4Cl at about the rate of one drop to 100cc of the nitrate. Just the proper amount of ammonium chloride it is not easy to specify. If too much be present the deposit will discolour on drying ; if too little, bubbles will collect on the cathode or the deposit will oxidise in the solution. Perhaps the surest way is to try a preliminary experiment, adding the NH_4Cl till the plate begins to show discoloration on drying.

If the solution is to stand the anode may be left in it. Care should be taken to exclude the air.

On removal from the solution the cathode should be washed thoroughly in running water and drained until it may no longer be said to be wet, after which gentle heat should be cautiously applied until all moisture is removed.

The advantages possessed by the nitrate may be enumerated as follows :

1st. The weight of copper deposited does not appear to depend on the current density.

2nd. It permits the use of a high current-density.

The limit is not easily stated. When 0·25 amperes per square centimetre is reached the cathode needs watching, for it will fringe at the edge but does not become powdery.

No way was found to prevent the branching with a high current-density.

A greater amount of NH_4Cl should be present when the current density is increased.

3rd. The weight of copper is practically independent of the temperature between 10° and 35° C.

The tendency to oxidation is increased by lowering the temperature, but this may be easily counteracted by the addition of more NH_4Cl.

4th. The solution may be used a number of times.

5th. The equivalent agrees to four figures with that calculated from the best chemical determinations, viz :

Richards Eq. = $(3294{\cdot}4 \pm 0{\cdot}1) \times 10^{-7}$
First Series Eq. = $(3294{\cdot}8 \pm 0{\cdot}43) \times 10^{-7}$
Second Series Eq. = $(3293{\cdot}9 \pm 0{\cdot}39) \times 10^{-7}$

The purity of the nitrate as a condition of success is to be emphasized. One specimen tried, which contained nitrite, was absolutely worthless with the foregoing treatment.

To see what $CuSO_4$ would do under circumstances similar to those in which the nitrate was studied, a saturated solution of the sulphate was rendered neutral by the copper hydrate precipitated on addition of ammonia. NH_4Cl was added until the deposit was as bright and lustrous as that formed in an acid sulphate solution.

Three such experiments yielded

Eq. = 3295×10^{-7}
Eq. = 3293×10^{-7}
Eq. = 3294×10^{-7}

These values tend to confirm the result obtained from the nitrate ; at least they do not contradict it.

In conclusion I wish to express my thanks to Prof. A. W. Wright, under whose direction the preceding investigation was made, for his many kind and helpful suggestions.

STEEL-PLATE PORTRAITS

Of Willoughby Smith; W. H. Preece, F.R.S. (President of the Institution of Electrical Engineers); Michael Faraday; Sir John Pender, G.C.M.G., M.P.; Sir William Thomson, F.R.S. (Lord Kelvin); C. H. B. Patey, C.B.; Dr. John Hopkinson, F.R.S.; Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S.; Prof. von Helmholtz; Prof. W. E. Ayrton; Lord Rayleigh, F.R.S.; Cyrus W. Field; Werner von Siemens; and Sir James Anderson, have been issued as Supplements to "THE ELECTRICIAN."

Copies of these admirably-executed Steel Engravings can be supplied price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price 4s. 6d., carriage paid (U.K.).

NOW READY.

Volume XXX. of "THE ELECTRICIAN," price 12/6; post free, 13/6 abroad carriage extra.

Cases for binding Volume XXX., price 2/0, post free, 2/3.

The Publisher is able to supply a set of the Volumes of "THE ELECTRICIAN" complete except for three Nos. Price on application.

ELECTRIC LIGHTHOUSE ILLUMINATION.

The reluctance of the Irish Light Commissioners and of the Brethren of the Trinity House to establish an electric lighthouse on the Old Head of Kinsale is, no doubt, based upon sufficient reasons, and can hardly be classed as another injustice to Ireland. Of the seven hundred and seventy lighthouses of the British Isles only six are provided with electric light. In no case where electric light has competed with other illuminants has such hot controversy raged, and such keen trade opposition been offered as in connection with lighthouses. The bitter semi-scientific discussion is now half-forgotten, but the development of electrical equipment for lighthouses has been almost at a standstill in this country; less than a dozen men have studied it. The opposition from motives of ordinary trade competition, seasoned, perhaps, for presentation to the public with a certain amount of humane and philanthropic affectation, has brought out a number of criticisms of the behaviour of electric lights. It has been nobody's business to collect statements on the other side, and the fact remains that powerful electric lights such as that at St. Catherine's Point dazzle some seamen in fine weather, compare unfavourably with oil lights to many when veiled by haze and mist, and are invisible at short distances to all in thick weather. It is not fair to suppose that the Trinity House hold up the cumbersome and wasteful arrangement at this lighthouse as a model. It was, doubtless, as good as could be got at the time, and the attempts to make a better lamp, using continuous current instead of alternate,

Digitized by Google

were a complete failure. In France, however, there has not only been a gradual development of electric lighthouse illumination since 1864, but after experience with no less than thirteen lighthouses, some of which have since been re-constructed, they appear to have arrived at a degree of perfection which renders any comparison between St. Catherine's Point and a good oil light quite useless.

Two Papers on electric lighthouses were read at the International Maritime Congress which met in London last month. One of these, by M. André Blondel, was a communication of considerable length. We print in another column an abstract of it. A good deal of attention was paid by the author to the design and to the characteristics of alternators for lighthouse work. This we have omitted in our abstract, for we fail to see any difficulty in this part of the work. If lighthouse engineers have not succeeded in getting alternators to suit their requirements it is probably because they were unable to give a specification to which manufacturers could work. Electro-platers were in the same difficulty for many years, and like lighthouse engineers, were content with very inferior dynamos. None of the leading makers of alternators would have any difficulty in building machines to suit the work, and those who desire to do so will probably find in the original Paper sufficient information to guide them. The details of the arcs are probably of much wider interest, and these will be found in our abstract. M. Blondel goes, perhaps, rather too far in suggesting that the separation between the carbons at St. Catherine's Point is only one-third of a millimetre, but he is quite right in saying that with only 35 to 38 volts "the surfaces of maximum brightness are almost completely shaded by the carbons." "In France," he says, "it is preferred to employ a genuine arc with a pressure of 45 volts, corresponding to a separation of 4 to 5 mm. for the current of 25 amperes, and exposing the bright surfaces." While the current at St. Catherine's Point varies from 180 amperes in fine weather to 300 amperes in thick weather (this maximum current being sufficient to make 40mm. cylindrical carbons red-hot), M. Blondel does not contemplate the use of more than 100 amperes. In clear weather the light need do little more than pass the geographical limit of visibility of the lighthouse, and any great excess will surely give rise to complaints about dazzling; but it is difficult to believe, even with the superior arrangement of French lighthouses, that the "foggy weather," which allows an arc of 100 amperes to penetrate 26 miles, is anything like the fogs that hang round our side of the Channel. Another branch of this subject, which, though of limited interest to manufacturers, is very attractive from a scientific standpoint, is the construction of the optical apparatus. A most complete and, of course, admirably illustrated description of the La Hève (Havre) lighthouse was given in *Engineering* a few weeks ago. The most striking improvement, due to M. Bourdelles, is the use of only four panels, the apparatus revolving in twenty seconds, and giving a brilliant flash, lasting one-tenth of a second, at intervals of five seconds. The St. Catherine's Point light has sixteen panels, revolving once in eight minutes, and giving gushes rather than flashes of light of a duration of five seconds, and at intervals of half a minute. Prof. Tyndall has pointed out that the spaces between these sixteen beams become filled with diffused light in hazy weather, while the beams lose their brilliancy, until not only is no flashing seen, but no fluctuation of the light is visible. A fixed light periodically cut off by a screen would show sharp flashes even if the light were so diffused that the source could not be seen. M. Bourdelles' "*feu-éclair*" by an increased rotary speed and reduced number of panels is probably better, owing to the lateral condensation of the beam. We hope that the hesitation of the Trinity House with regard to the Old Kinsale Head is due to the consideration of some of these very important French developments rather than of the "monster lens" which is promised to magnify a big oil lamp to the confusion of all electric lights.

REVIEWS.

The Dynamo. By C. C. Hawkins and F. Wallis. (London: Whittaker and Co. 1893.)

The theory and design of the dynamo has been treated by almost all authors in a very ponderous fashion. They have collected notes on the observed behaviour of dynamos, and have cast them into the form of theories, and they have vied with each other in endeavouring to build up comprehensive formulæ, by combining together a number of distinct arithmetical operations. In continuous current machines, at all events, whatever ambiguities may arise with alternators, there are two principal parts called the armature and the field-magnets. It would seem to be the aim of some authors, not to reduce, but to elaborate their work, until they arrive at two formulæ, one for the armature and one for the field. Interesting as this may be to mathematicians, it does not appeal to engineers. Engineering construction is an art, and it is useless to attempt to reduce it to a pure science.

The book before us is remarkably free from mathematical complications, and, with one or two exceptions, there is no tendency to cover too much by one formula. In several respects the authors have treated the subject in an original style. There are, for example, twenty-two chapters, but the magnetisation of iron is not discussed until the twelfth, and characteristic curves are not described until the sixteenth chapter. It is addressed to students, and an elementary acquaintance with electrical science is assumed. The book is, however, sure to fall into the hands of engineers, to whom it will, indeed, be very useful; and a word or two of further explanation is required here and there for those who have picked up a general knowledge only of electricity. In explaining the connection between the ampere-turns on a solenoid and the C.G.S. strength of field, the formula $H = k \cdot A\,T/l$ is used, and k is simply stated to be "$0{\cdot}4\,\pi$, or 1·256." The appearance of $4\,\pi$ and of the divisor 10 could have been explained in five or six lines in a foot note. In several of the earlier chapters unipolar dynamos are referred to. In one place too much attention seems to be devoted to hypothetical machines of this kind, but later on we find the Mordey alternator is given as an example of the unipolar type. It may fall under the author's definition of a unipolar dynamo, but it would seem better to restrict this term to such machines as those of Siemens and Forbes, both of which are very properly omitted from the present work, as being of minor importance. The chapter on armatures may be read with interest by anyone who has already a fair acquaintance with dynamo building, but for a student or for a mechanical engineer a few more simple diagrams should be provided.

For the first time in the literature of dynamo construction the question of magnetic leakage is adequately and practically discussed, with the free use of the words reluctance and permeance, and the more generally understood and more important question of heating is dealt with at greater length and thoroughness than has yet been attempted. The portions of the book relating to these two questions require a little simplification before they are fit for use in the drawing office; to reduce them to a few definite and practical rules is no difficult matter. Descriptions of obsolete machines and laboured dissertation on the comparative merits of long and of short shunt are absent, but one or two practical matters are either omitted or are passed over too lightly. The importance of true balancing of armatures and the fallaciousness of the knife edge test should be insisted on. Instability of field is alluded to more than once, but more distinct warning should be given about

Digitized by Google

it. The use of two wires in parallel for armature winding, when the calculated size does not agree with any stock or standard size, is suggested; but we do not find any corresponding hints for making up a shunt winding under similar circumstances, and the precautions to be observed when it is necessary to use two different gauges in series. It is probably seldom that dynamos have to be designed without the use of a table of copper wires, but in the event of such a case the authors give a very convenient rule, which is worth extracting. The resistance of 1,000ft. of copper wire of 100 per cent. conductivity, at 60°F, and having an area of 0·09 sq. in., is 0·09 ohm; or the resistance of a wire of 0·05 sq. in. is very nearly 0·05 ohm per 100 yards. Alternators are but briefly discussed, and the authors do well to leave this part of the subject until the theory has emerged from the present chaotic stage, and until alternator builders have established something better than a rule-of-thumb practice.

There is, probably, very little fresh to be said about dynamo construction, and all that an author can do is to carefully collect and arrange, and to reduce to engineering practice principles which have been already arrived at by theory or by observation. The authors have naturally availed themselves of the writings of Hopkinson, Kapp, Swinburne, and Esson, but in several cases a little more condensation might have been effected. In the absence of any good text books on electricity and magnetism, the first six chapters are perhaps necessary. They form an excellent introduction to the main purpose of the work. We should like to see a more marked distinction between this theoretical part, which should be learned at college, and the account of the construction and designs of dynamos, which cannot be properly learned anywhere but in the workshop and drawing office. We welcome this book as a thoroughly trustworthy and useful work.

Electrical Tables and Memoranda. By S. P. Thompson and Eustace Thomas. (London: E. and F. N. Spon.)

This little pocket-book, measuring $2\frac{3}{4}$in. by 2in. by $\frac{1}{4}$in., suggests by its title the proper aim of a pocket-book—tables and memoranda. Tables in the first place, for it is impossible to remember a table, and memoranda in the second place; but these should be confined to matters which are difficult to remember. Some tables consist of the mere working out of a simple formula, entailing a single arithmetical operation. To print these in a large pocket-book, instead of the formula, is a matter of labour-saving. Such, for example, are the tables of circumferences of circles and conversion of thermometer scales. The present pocket-book contains about twenty tables, but is cumbered by none of this simple class. In a larger book, labour-saving tables are useful, and might sometimes be accompanied with advantage by diagrams giving the same results in the form of curves. The **B H** curves of soft annealed iron, iron hardened by stretching, steel, and steel glass hardened, are given on a very small scale, the diagram being only about 1in. square and the scales given without square rulings. A numerical table of **B**, μ, and **H** of annealed wrought-iron and of grey cast-iron is given, and occupies three-quarters of a page. One of the advantages of giving such information in the form of curves is that a considerable number of curves may be drawn on one diagram and occupy no more space than a single one. The limit is only reached when the curves become so numerous, or cross each other at so small angles, that there is a difficulty in following them.

It is rather difficult to criticise the memoranda in this pocket-book. The authors offer certain morsels of information which are no doubt memoranda in the sense that they are worthy to be remembered; but if this were the sole criterion we could not complain if a list of the days of the week were included. A good deal of condensed text-book matter, laboratory notes, and workshop instruction is given, all excellent of their kind, but we think unsuitable for a pocket-book in which space is, or should be, so valuable. It is not difficult to say if a text-book be complete or not complete; it should contain all that is necessary to be known up to a certain point, depending on its size. But a pocket-book of this kind should not attempt to give new or original information, but should consist of well condensed matter which is difficult to remember. A short trigonometrical table appears to us to be indispensable, even if limited to sines, cosines, tangents and cotangents of angles. No such table is given, but a short table of logarithms is provided. Logarithms must be classed with labour-saving tables. No one can judge what is easy or what is difficult for another to remember, and unlike text-books, the more pocket-books there are the better, so that each can choose for himself the one that is best suited to supplement the particular shortcomings of his memory.

Handbook on the Steam Engine. By Herman Haeder. English Edition. Translated by H. H. P. Powles. (London: Crosby Lockwood and Son.)

The vagueness of the term "handbook" is again illustrated by the title and contents of this work. We have here what, except for its size and shape, would ordinarily be termed a pocket-book, inasmuch as it is a collection of tables and dimensioned drawings of steam-engine details, for use in an engineer's drawing office.

The data are entirely empirical, being based, not upon considerations of stress and strength in the details to be designed, but upon what, for want of a better term, we may call the "method of imitation." This method consists in designing or drawing in strict proportion to some established pattern, details of the proportions of which are tabulated in the book. The process is not uncommon among draughtsmen, and is perfectly safe as long as the draughtsman understands the principles of his work and the reliability of the materials he is proposing to use. The danger in such a work lies in its tendency to create machine-made draughtsmen, who, as long as the work does not carry them off the lines of established practice, are able to compete with superior and fully qualified men, but who, directly they are faced by something entirely new, either fail to produce a design or, worse still, produce one which conceals faults which may end in disaster.

It is, of course, of great value to possess in a compact volume the tabulated practice of so many English and Continental firms of engineers as is to be found in this work, and we have no hesitation in saying that as such the book ought to find a ready place in drawing offices. It abounds in diagrams of engine details, about which, if we can have any complaint, it is that they are in many cases too small. The large plate showing very clearly the internal arrangements of a Willans central valve engine would have been more serviceable had it represented the later pattern of that engine, into which many important improvements have been introduced.

Lecons sur L'Électricité. By Eric Gérard. Third Edition. Two vols. (Paris: Gauthier-Villars. Liége: Léon de Thièr. 1893.)

We have already reviewed at some length (see *The Electrician*, Vol. XXVII., p. 327) the former edition of this excellent work; and we, on that occasion, congratulated the French student upon his having available so comprehensive, so scientific, and so clearly written a work as the one before us. Considerable additions have been made in the third edition, and the various sections give evidence of having been brought well up to date. Among these new features we notice sections upon polyphase motors, electrometry, new dynamos, traction, and lighting. Two new and important chapters have been added, the one dealing with telegraphy, the other with telephones and the combination of telephony with telegraphy on the same circuit. The author also discusses some of the latest developments in the theory and use of alternating currents. While this work is confessedly to a large extent a compilation, it is none the less valuable on that account; for the utmost care has evidently been exercised in the choice of suitable material, and copious references are given to the sources from which information has primarily been obtained.

Alternating Currents of Electricity. By Gisbert Kapp. (New York: The W. J. Johnston Company.)

This small and elementary text-book has been reprinted from the "Professional Papers of the Corps of Royal Engineers," with an introduction by Mr. Wm. Stanley, jun. It is quite evident, though there is no direct intimation of the fact, that the book contains the substance of a series of lectures. It is a great pity when traces of a lecturer's style, in using such phrases as "I have here a coil," or "You will observe the diagram on the wall," or "I use the bottom of an ordinary

Digitized by Google

biscuit tin," &c., are left in all their nakedness for the eye of posterity. A little careful revision would turn what looks like a *verbatim* lecture report into palatable and instructive reading, for, however admissible such phrases may be in the record of a society's proceedings, they do not help the reader of a text-book. The first four chapters of the work are devoted to an explanation of alternating currents and their measurement; the next three to the principles and design of alternators and transformers. Chapters VIII. and IX. describe some alternating-current stations, and Chapter X. deals with methods of parallel running. The remaining chapters relate to alternate-current motors and the use of multiphase currents. There is a general belief that text-books of alternating currents are almost synonymous with higher mathematics; and the difficulty hitherto has been to produce a readable and useful book for non-mathematicians. Mr. Kapp has attempted to cut the Gordian knot by transferring the difficult mathematics, of which there is not a great deal, to a series of short appendices.

The Management of Accumulators. By Sir D. Salomons. (London: Whittaker and Co.)

This little work forms the first volume of the seventh edition of a work which has previously been known under the title of "Electric Light Installations and the Management of Accumulators." We understand that the work has been revised and enlarged, making it necessary to publish it in more than one volume. The first volume embodies the results of the author's experience in the management of secondary batteries for private electric lighting work.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 446.)

The filaments must, of course, be measured before mounting and flashing, and it is well to measure them again after flashing, to see that the increase in thickness is of the proper amount. The measurement may be done in several ways by means of micrometer gauges, or by throwing a magnified image of the filament upon a screen by means of a lamp and lens, or by the ordinary microscope method, which, however, cannot be considered a factory method. Measuring with a micrometer can only be done with accuracy after a considerable amount of practice. The best form of micrometer to use is that represented in Fig. 21, which can be read to the fifth part of a mil. It should be mounted on a support fixed to the table, so as to be about three inches above the table, and so that the screw head can be turned easily with the thumb and fore-finger of the right hand, with the fore-arm resting comfortably on the table. The filament will be held very lightly between the thumb and fore-finger, or between the first and second fingers of the left hand. Great delicacy of touch is required, as the filament may be squeezed to a considerable extent, and the measurement will be wrong. Some micrometers have a ratchet-head, so that they may be screwed up until the object to be measured is held just so tightly that the ratchet head slides round without closing the gauge any further. This arrangement is, however, not sufficiently delicate for filaments. They may be squeezed much too tightly before the ratchet comes into play. Of course a ratchet-head might easily be made to work with a very slight pressure, but the difficulty is to get one which will turn the micrometer screw without anything in the jaws, a considerable force being required to do this, and yet which will slip on the slightest extra resistance. A micrometer without the ratchet-head may be used, and it can be screwed up until it is felt that the filament is being touched, but it is difficult always to squeeze to the same extent. A much more accurate plan is to slowly move the filament backwards and forwards in the direction of its length between the jaws of the micrometer which are steadily and slowly being screwed up with the other hand. Immediately the filament is gripped, ever so lightly, it will be felt by the fingers holding it, before, indeed, the fingers of the other hand turning the micrometer feel the resistance at all. Filaments can in this way be measured very accurately. When the filaments are not properly circular there is sometimes a difficulty in getting the greatest measurement, as the micrometer will tend to turn the filament round so that it measures always its least diameter.

The method of projecting a magnified image of the filament or a part of it upon a screen is very accurate if properly carried out, but it requires two person to work it, one to put the filaments in position, and the other to read the result on the screen, if the measurements are to be made as quickly as with the screw micrometer. The larger the image the more accurately can it be measured on the screen. There are, however, two difficulties in making a large image. Either a very short focus lens must be used, in which case a slight error in the position of the filament will make a considerable error in the size of the image, or, if a long focus lens is used, the distance from the lens to the screen will be inconveniently great. In any case, an achromatic lens should be used, or the image of the filament will be blurred, on one side in red and the other in blue.

If the filament is magnified one hundred diameters, the screen may be divided in tenths of an inch, in which case each division will represent one mil in the filament. The screen may be made to slide either in a vertical or horizontal direction, according as to which way the filament is held, so that the zero line of the scale may be brought to the edge of the image of the filament. Another method is to use a scale

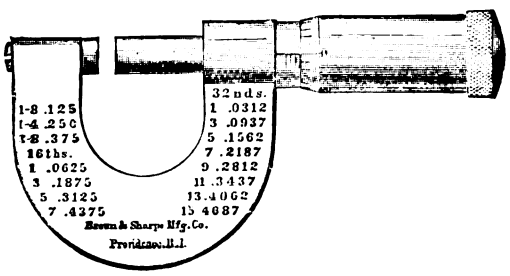

Fig. 21.—Micrometer Gauge, for Measuring Diameter of Filaments.

drawn on glass, the image of which is thrown together with that of the filament on to the screen. There is a slight error here, as the scale must, of course, be either in front or behind the filament, and will, consequently, be either a little too large or too small. This error will be unimportant if the lens be an inch or more in focal length, though the image of the scale may not be quite sharp. If the lens has a focal distance of one inch, the distance of the screen from the centre of the lens will be 8ft. 5in., while the filament will be 1·01 inches from the centre of the lens. This is rather inconveniently close for the handling of the filaments, but a greater focal length of lens requires a correspondingly greater distance to the screen. A lens of three inches focal length gives more room, but the distance of the screen will then be over 25ft. A powerful illumination is required in order that the image on the screen may be easily distinguished. An incandescent lamp similar to those made for lantern purposes answers very well, the light being concentrated on the filament by a condensing lens in the usual way. This method is very useful in determining the diameter of a filament after it has been made into a lamp, the filament itself being rendered incandescent. The filament is placed in the right position by getting it in line between two fixed wires or narrrow slits in metal plates on either side.

A lamp bulb is one of the very simplest things which a glass worker can have to make. Everything which is made direct from the glass pot is, in fact, made first of all into a bulb in some form or other. Pressed glass is, perhaps, the only exception, as it is merely a lump of glass dropped into a mould and pressed. This, however, does not mean that there is no skill required in the making of a lamp bulb. The method of working is as follows: The glass worker has an iron tube some five or six feet long; he dips the end of it,

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

Digitized by Google

after first heating it, into the molten glass and "gathers" some glass on the end. There is considerable skill required in gathering the right amount. He then withdraws the tube, and holding it out in a somewhat inclined position, the end with the glass upon it being higher than the near end, he blows through the tube, at the same time turning it round and round, and in this way forms the glass into a hollow bulb. If he wants the bulb to assume a long or pear shape, he whirls the tube round and round as one may twirl a walking cane. It requires much skill to produce bulbs of the same size and shape in this manner, but good glass workers are able to make wonderfully uniform bulbs in this way.

There is, however, another method, not requiring so much skill, by which the bulbs are all made exactly of the same size. They are blown into a mould, such as shown in Fig. 22. The mould is made of iron, and is lined with plumbago. The glass worker, having gathered some glass on his iron tube, stands on a low platform or stool, and places the end of the tube with the glass on it in the opening of the mould, which a boy holds in position on the ground. He blows down the tube, and twirls it round between his hands at the same time. The glass is blown out so that it fills up the space in the mould. The boy then opens the mould, and releases the bulb, which is then cut off from the tube. Wooden moulds may be used if only a few bulbs of an odd size are wanted. Apple wood answers the purpose. The bulb is blown in just the same way. The surface of the mould quickly becomes charred or carbonised, and thereby protects the wood below the surface. A number of bulbs may be made in it before it perceptibly increases in size. Pump bulbs and the like may

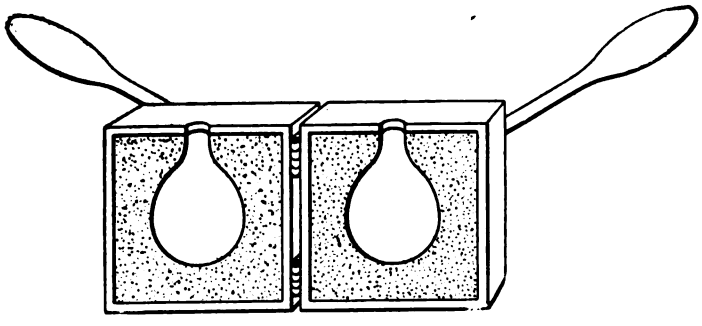

Fig. 22.

very well be blown in wooden moulds, as also may the globes or shades for the flashing apparatus. For these latter the mould need not be so complete. It is sufficient if the mould be simply a cylinder open at both ends.

The only other article required in a lamp factory, made directly from pot glass, is glass tubing. Quantities of this of various sizes are required. Small sizes are used for making the tubes which are joined to the bulbs, and through which the air is exhausted; and larger sizes for the mercury pumps and other apparatus. The method of making the tubing is very simple. The tube begins, as most things do, with a bulb at the end of the glass worker's iron tube. A lump of glass is first gathered from the pot upon the end of an iron rod, which is then given to a boy to hold, glass uppermost. The glass worker then gathers glass on his iron tube, in quantity according to the size of the tube he is going to make, and forms it into a hollow bulb. If the tube is to be of large diameter it will be a large bulb, and will require a good deal of rolling on an iron plate, and re-heating at the mouth of the crucible before it is of the proper shape. It must be perfectly round inside and out, or the tube will contain along its whole length any defect in the shape. Having got the bulb into the required size and form, the glass worker turns it over so that the end of it is brought into contact with the glass at the end of the rod which the boy is holding in readiness to receive it, and to which it will adhere. The iron rod and the tube are then both held horizontally, and are turned round and round, while the boy at the same time walks backwards, thus elongating the bulb, and drawing it out into a long tube. The tubing is made in this way many feet long. For a considerable length in the centre of the piece it is, probably, of nearly uniform size, though towards each end it will be larger. When it is pulled out sufficiently, and becomes rigid, it is laid on the floor across pieces of wood placed ready to receive it, and is then cut up into lengths, which are afterwards sorted into the different sizes. A good glass worker can so manipulate the glass as to produce within a very little the exact size of tube which is required.

The art of glass-blowing consists in softening glass in a blow-pipe flame, and then working it into the desired shape or form. The incandescent lamp industry has had to produce its own glass blowers. In the early days of incandescent lamp making there were few skilled glass blowers, and many of them were only skilled in making perhaps one particular article. Thus, a man who was used to making spiral-bulbed thermometers would in all probability be a very poor hand at "sealing in" a lamp filament. He would demand an extortionate rate of pay, and would work excessively slowly, and he would not work at all if anyone was standing by, as he did not wish to give away the secrets of his trade. It was on account of this kind of thing that Messrs. Wright and Mackie brought out their glass-blowing machine, a machine specially designed for making lamp-bulbs out of tube, and for sealing in the filaments, all without the aid of the professional glass blower. Bulbs made straight from the glass-pot—"pot bulbs," as they are sometimes called—were not made at the time. The bulbs were all made from the tube. The glass-blowing machines, however, never came into general use, partly on account of the introduction of pot bulbs and partly because it was found that a new race of glass blowers, without the prejudices of the old hands, was springing into existence. It was

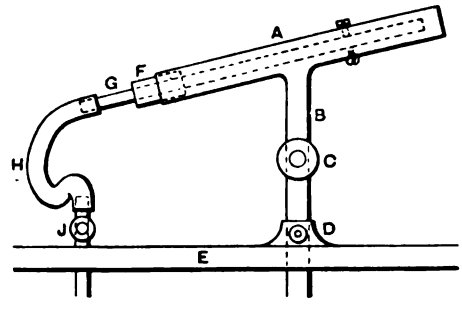

Fig. 23.

found that lads who were handy with their fingers could soon learn not only to seal in, but even to make good bulbs, and many of them even to do the more difficult work of making pumps. A lad or a girl at a fraction of the wage of the professed glass blower would do more work, and yet be well paid.

Complicated glass work for chemical and other apparatus, which many glass blowers were accustomed to make, is of necessity done in a very slow and deliberate manner. A moment of impatience, too quick heating or insufficient annealing of a part, might spoil a whole day's work. This is no doubt the reason that glass blowers appear to work so very slowly. Such a slow rate is, however, quite unnecessary in lamp making. The really skilled glass blowers are not found in lamp factories, for the reason that they are not required, and that it pays them much better to make chemical and other apparatus, which always commands a good price.

The blow-pipe most commonly used in glass-blowing is that called the "cannon." Various forms of this blow-pipe of a more or less elaborate construction, are made, but the simplest and cheapest form, shown in Fig. 23, is the most satisfactory. It consists of a piece of brass tube, A, open at both ends, joined to another tube, B, at about the angle shown in the figure. C is a screw stop-cock. D is a socket through which the tube B slides, so that the whole can be raised or lowered and fixed by the thumb-screw in D at any convenient height above the table E. Below the table the tube B is joined by a flexible tube to the gas supply. F is a cork with a hole bored through its centre to accommodate a piece of glass tube, G. About two-thirds up the tube, A, three screws pass through it and act as guides to the inner glass tube, G, and keep it in

Digitized by Google

the centre. The end of the glass tube G is joined by a piece of flexible tube, H, to the air-blast through the stop-cock J.

Almost any kind and size of flame may be obtained with this blow-pipe, depending on the regulation of the gas and air blast by the cocks C and J. It is necessary, however, to use a larger bore glass tube, G, for the large flame than for the smaller ones, while for the small pointed silent flame the nozzle of G must be considerably contracted. It is a matter of importance that this glass tube be quite straight and regular and smooth inside, and that both ends of it, especially that from which the air issues, be cut off perfectly straight across and at right angles to the tube. This tube can be shoved in and out through the cork and adjusted to its proper position. It should not reach to the end of A by a quarter of an inch or so.

(To be continued.)

OCEAN TELEPHONY.*

BY SILVANUS P. THOMPSON, D.SC., F.R.S.

(Concluded from page 440.)

CASE 2.—*Use of Mutual-Induction Devices Distributively.*

In this case the cable is considered in sections, each of which is in inductive relation with those on each side of it; and again there are many possible varieties included. One example is as follows:—Let the two conductors along the cable be each divided into a number of equal lengths, and let the parts be joined together by mutual-induction coils, that is to say, by induction coils with two windings each. Though the

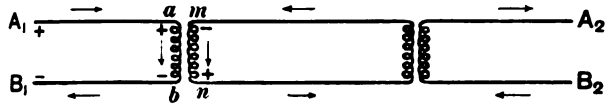

FIG. 7.

exigencies of cable-laying will necessitate some very different shape of coil or device as an organ of mutual induction, we may assume these induction coils to be of the familiar form of an iron core surrounded by the two windings. The cable so made up of sections will be indicated by Fig. 7.

In this figure it is indicated that the coils are so connected that in the A line when the current is increasing and flowing

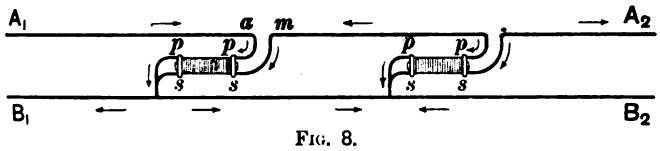

FIG. 8.

toward *a*, the inductive action will be causing a current in the next section, which will be at the same instant increasing, but flowing, so far as the A line is concerned, in the opposite sense, so that while the potential of the point *a* is rising that of the point *m* is falling. The consequence will be that the currents required to sweep out any accumulated charges due to capacity will not have to travel (as in ordinary cables) all the way from the ends of the cable, but need only travel short distances, never more than the length of half a section. Hence, if a cable

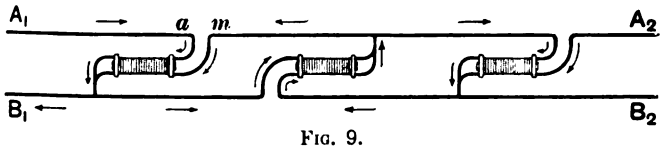

FIG. 9.

2,000 miles long is cut up into 25 sections of 80 miles each, there should be no more retardation than on an ordinary cable 40 miles in length. It is not needful that both the lines should actually be divided: a virtual division into sections is effected in Fig. 8, where the B line is actually continuous. In this figure *p p* is the primary, and *s s* the secondary (or *vice versâ*) of the mutual induction coil. Or the arrangement may be alternated, as in Fig. 9.

Or again, if three conductors are employed—of which one may be the sheathing—the sectioning and use of mutual-induction may be accomplished as shown in Fig. 10.

Here, again, as remarked above, the kind of induction coil which naturally suggests itself as suitable for the purpose in question is something of elongated shape, such as a

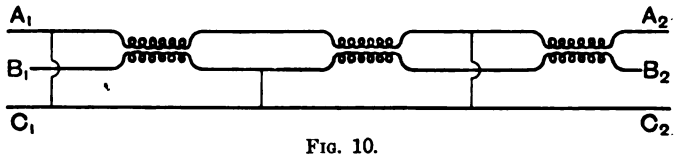

FIG. 10.

very elongated loop "shell" transformer, or the "cable" transformer which was suggested for electric lighting purposes by Messrs. Siemens and Halske some years ago. Or, as the author suggested in 1891, by using a mutual induction between the wires of the cables themselves by merely enwrapping them, as they lie side by side, with iron. So that the cable once more becomes an arrangement of three parallel

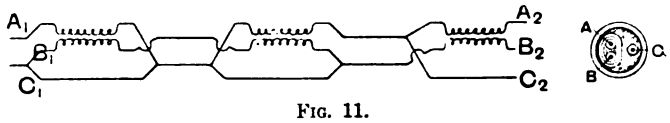

FIG. 11.

wires, of which two are specially brought into mutual inductive relations to one another, and are joined up at intervals, as indicated in Fig. 11.

Lastly, it is, as is well known, possible to have mutual induction between two wires that do not form part of closed circuits, as in the phonopore of Mr. Langdon Davies.

III.—EVIDENCE AS TO PRACTICABILITY OF USING INDUCTION DEVICES DISTRIBUTIVELY TO COMPENSATE RETARDATION.

With the facts already known that the Varley shunt does indeed operate at the ends of a cable to compensate in some measure the effects of capacity near those ends, and that on long landlines the speed of signalling can be increased by inserting a translator in the middle, or even by a mere leak at some intermediate point, it is remarkable that no one should have suggested hitherto the very simple solutions now proposed. Perhaps the reason is to be found in the intense horror with which all good telegraph engineers regard the idea of having a fault on their line. Deliberately to insert, as the author proposes, a series of faults, as shunts across the cable from the going wire to the return wire, will, to many of them, appear sheer madness. The shunts are not mere faults, however. They are bridges possessing considerable resistance, and, what is more to the point, considerable self-induction. They are not leakages, through the insulation to the sheath, of an unknown amount, and one liable to increase by corrosion; they are as fixed and determinate as the resistance of the cable itself. Telegraph engineers have long known in general the virtues of an inductive shunt. In the third volume of the *Journal of the Society of Telegraph Engineers*, 1874, Mr. G. K. Winter describes the use of inductive resistances in cable signalling, such shunts being used at the ends of the cables, as Varley had previously used them. The idea of using such Varley shunts distributively along the cable appears to have been vaguely in the mind of no less eminent a telegraph engineer than the late Mr. Willoughby Smith, who, in 1879, read a Paper on the working of long submarine cables to the Society of Telegraph Engineers. In this Paper, after recounting some experiments made with Varley shunts—or what he seemed to think such—he adds: "I was under the impression that by a judicious distribution of electromagnets on subterranean lines greater speed might be obtained." But he seems to have been deterred from following out the idea by finding that the solid core electromagnets which he was using failed to operate favourably; and he even declared that such minute currents as were used in cable signalling were "totally inadequate to produce perceptible electromagnetic induction

* Paper read before the International Electrical Congress at Chicago, August 22nd.

Digitized by Google

effects." We now know from telephonic experience that this is not so; even the minutest telephonic currents being perceived, simply because they can produce sensible electromagnetic effects.

Other electricians have proposed to use shunts containing electromagnets from line to earth for various purposes. Amongst them Mr. Lockwood and Mr. Edison. The latter in his patent, No. 135,531, applies such shunts to overcome the static charge on lines. The author in 1884 proposed to apply such shunts to enable him to introduce a battery current into a telephone line without diverting the working telephonic currents. Again, it has been found in telephone work that a telephone receiver placed across from line to earth, as a shunt or bridge, does not prevent another receiver further down the line from receiving its proper current. This bridge method of arranging telephonic instruments has for years been used in the British Postal Telegraph service. In 1890 a most suggestive communication was made at the Detroit Convention of the American Association by Mr. J. J. Carty on "Bridging Bells," in which he described arrangements of way-lines in which the electromagnets of the bells instead of being inserted in the lines (where their impedance would prevent telephonic talk), were set as bridges or shunts from line to earth. He found * a way-line with eight such shunts upon it at eight intermediate stations to transmit speech *better* than it did with only two stations. In this case the coils used had resistances of 1,000 ohms, as measured on the Wheatstone bridge; but, with a magneto-generator giving an alternate current the impedance was about 10,000 ohms. Again, when in 1891 the London-Paris telephone line was constructed by Mr. Preece, with a special cable about 20 miles in length from Dover to Calais in the middle of it, the circuit being metallically closed, it was found that the talking from London to Paris was in no way interfered with when telephonic receivers were bridged across the circuit at the two ends of the cable. In fact such bridging rather improved the working of the line. It is therefore reasonable to suppose that by systematising the arrangements, of which more or less imperfect glimpses are afforded in these instances, and by providing a cable with inductive shunts at proper intervals all along so as to balance the capacity from point to point, in a distributive manner, the longest cable can be made to transmit speech, and if speech, the less frequent impulses of automatic telegraphs.

Many experiments have been made in the author's laboratory with arrangements of apparatus set up to imitate by condensers and resistances the retarding properties of actual cables. An example will suffice. A section of artificial cable was made up of a resistance of 7,000 ohms, and a capacity across between line and earth of 10 microfarads. Through this cable not a sound could be transmitted telephonically to a double-pole Bell receiver at the distant end, either with a Blake transmitter (with induction coil) or with a Hunnings transmitter without induction coil. When, however, a single compensating self-induction coil, having a resistance of only 312 ohms, and a time constant of about 0·005 second, was bridged across at an intermediate point, telephonic transmission became at once possible, save for very shrill sounds.

One curious result came out in one of the series of experiments, namely, that those telephonic transmitters which have induction coils in them (the ordinary mutual-induction coils with thick and thin winding), are almost useless for the purpose of cable transmission. Apparently the fine-wire winding has too great a self-induction in series in the circuit to be suitable for this purpose. At any rate, better results were obtained from transmitters of other types. Quite recently the author has got better results from a transmitter in which the ordinary two-wire mutual induction coil was replaced by a single self-induction coil on a plan suggested by him in 1884. It is obvious that any plan which contemplates the counterbalancing of retardation by shunting (through self-induction coils) a notable fraction of the current may necessitate a new type of transmitter capable of sending telephonic currents of much greater amperage than those ordinarily used in overland telephony.

* See *Electrical World*, Vol. XVI., p. 208, 1890.

So far, the evidence for the effective operation of self-induction has been considered. But there exists also much evidence to show that mutual induction by devices properly distributed along a twin-wire cable will also be effective in neutralising the retardation due to distributed capacity. It is an old and well-established rule that the retardation in a cable is proportional to the square of its length. If one could cut a 2,000 mile cable into two cables of 1,000 miles each, and simply translate or relay the current from one into the other, the retardation of the whole ought to be reduced very materially, perhaps not to one quarter, but at least to one-half. Only here, again, it is evident that some of the electric energy supplied at one end must be used up in the act of working the translator or relay, however it is constructed, even if it be only a simple mutual induction coil. Therefore, if a cable is cut up into numerous sections, each connected by mutual induction with the next, a considerable fraction of the energy put in at one end may never reach the other, being spent on the road in overcoming the retardations that would otherwise arise. For land lines it has often been proposed to cut up the line into parts, as for example, by Edison in his patent No. 150,848, in which for the attaining of greater speed he shows a line divided at three intermediate points where the circuit is grounded through mutual induction coils. The objection to ordinary induction coils for this purpose is that they are never well enough made from the inductive point of view. If they are not so constructed that *all* the magnetic flux due to one of the sets of coils interlinks itself with the other coil, then each coil will possess an unbalanced self-induction, and will offer an impedance. Mutual induction, as is well known, tends always to wipe out the self-induction of both the circuits thus brought together; but with the most perfect conditions of magnetic circuit, the utmost that the mutual induction can effect is to neutralise the self-induction

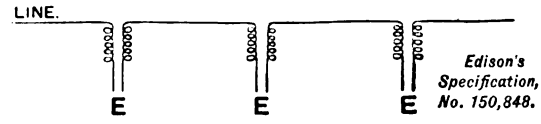

Fig. 12.

only of those coils which are acting as mutual inductors. It cannot neutralise the self-induction in parts of the circuit beyond. Hence, for the particular purpose in question—namely, that of enabling the circuit to transmit telephonic signals—the induction devices must not be simple ordinary coils inserted haphazard at intervals; they must be specially designed and inserted with perfect regularity. And the cable itself must be freed as far as possible from self-induction. *Never, for such a purpose, must a cable be constructed, as Atlantic cables have hitherto been, of a single conductor* (of stranded copper) *surrounded by an iron sheathing* that comes in between the outgoing and the returning parts of the circuit, thus adding an enormous impedance. Happily, in all twin cables where outgoing and returning conductors lie side by side within the sheath, the iron of the sheath, enclosing both, increases the mutual induction between them. As the author pointed out in 1890, in the discussion on the London-Paris telephone line, the mutual induction of the twin cable is a positive gain, enabling transmission to take place far beyond the limits previously assigned from considerations as to capacity and resistance alone. In such constructions as Fig. 6 the iron used to increase the self-induction of the wires that act as compensators will of itself increase the mutual induction between the twin conductors if they are properly disposed. The experience gained with alternate-current working is absolutely conclusive as to the efficient action that may be expected in special constructions for future ocean telephony.

IV.—Conclusion.

Ocean telephony is possible. The means for attaining it are within our grasp. Compensated cables of the new type are entirely practicable. It may be needful to begin with some shorter line than an Atlantic cable, in order to gain experience. But an Atlantic cable constructed on the new

Digitized by Google

plan will not cost much more, when laid, than one of the old type; and whether or not it is successful in conveying telephonic speech, it will certainly transmit telegraphic messages at a greatly accelerated speed of signalling. If one Atlantic cable can be constructed to do the work now requiring eight cables, that cable will be constructed. Acceleration of the ocean telegraphic service is in itself a desirable step in advance; but the advance will not be complete until telephonic speech is transmitted also from shore to shore.

THE AZORES CABLES.

The opening of cable communication between Lisbon and the Azores Islands was inaugurated by the King of Portugal on the 27th inst. at the Eastern Telegraph Company's station at Carcavellos, near the Portuguese Capital, in the presence of the leading officials of the country and some 400 distinguished guests.

The negotiations for laying this cable have been carried on for some 20 years, and finally, after a keen competition with the French Société des Téléphones, who last year secured the concession, but allowed it to lapse, it was granted to the Telegraph Construction and Maintenance Company, who laid the cables within about two months from the signing of the contract, a promptitude which forms a record.

The sections, with their approximate lengths, are as follows:—

Lisbon to Ponta Delgada, St. Michael	940 knots
Ponta Delgada to Horta, Fayal	200 „
Horta to Island of Pico	5 „
Pico to Island of San Jorge	12 „
San Jorge to Island of Gracioso	25 „
San Jorge to Island of Terceira	30 „
Total	1,212 knots.

The first two cables are to be worked by the Europe and Azores Telegraph Company (Limited), of which Sir John Pender is Chairman, which is to take over the cables from the Telegraph Construction and Maintenance Company; and the inter-island cables are to be worked by the Portuguese Government.

The Azores, and especially Fayal, have long been recognised as a health resort, and now that the islands are in telegraphic communication with the rest of the world, no doubt an increased number of people will visit them. The climate is delightful, the range of temperature small, the scenery exceedingly fine, and living very cheap. No doubt, also, now that it is possible to telegraph, additional shipping will call, especially as coal can be obtained either at St. Michael or Fayal. A Portuguese lines of steamships runs from Lisbon to the different islands. Telegraphic communication will also have some value for meteorological purposes, as many of the storms which pass over America in an easterly direction are dispersed, and do not reach this country; and, as there is no available island in the North Atlantic which could be placed in cable communication with Great Britain, telegrams from the Azores will in some cases enable more accurate forecasts of the weather to be made. Fruit of almost all kinds grows freely at the Azores, and a considerable trade is done with Europe. At one time St. Michael oranges were famous, but for some reason the quantity of this fruit produced is very much less than it used to be. The Azoreans are "Home Rulers," and wish to have the right to manage their local affairs. It is to be hoped and expected that the telegraph will increase the prosperity of the islands, and serve to develop Portuguese commerce and enterprise.

The march of the telegraph is ever onward—*sub mari per terras*. Some years ago it was said that there would be little work in the future for cable manufacturers, but each extension in time requires its duplicate and triplicate or alternative lines, and in many cases necessitates further extension. It is only 27 years since ocean telegraphy was proved practicable, and now there is no important place or port of the world which is not connected with the great network of international telegraphy which, octopus-like, stretches its tentacles all over the civilised globe. There are about 150,000 miles of submarine cable, and over 2,000,000 miles of land line. To-day the Azores are connected, and before the end of the year the Seychelles and the Mauritius will be placed in telegraphic communication with all parts of the world.

HIGH-SPEED RAILWAYS.

It is popularly supposed, and there are, we fear, men calling themselves engineers who share the idea, that the problem of rapid transit simply consists in getting more power into a locomotive so as to enable it to overcome the various resistances at a higher speed. This, while it undoubtedly is one of the points to be developed, is not the only nor the most important detail in the problem. The conditions which have led to a speed of sixty or seventy miles an hour becoming the limiting speed of railway transit are by no means confined to the structural difficulties involved in designing a steam locomotive to draw a train at a higher speed. On the contrary, there is no good reason for supposing that a high-speed locomotive would be impossible of construction. The practical difficulties are to be found mostly in the construction of the permanent way; the remaining difficulties being principally of a financial nature, and relating to the increased cost per train-mile as the speed is increased.

The existing steam railway lines are invariably designed to suit a definite limiting speed of transit; and the advent of a more rapid locomotive would not accelerate traffic over these lines Three principal points are kept in view in this relation, namely, the design of the rail section and gauge, the setting off of curves and of the transition gradients. The greatest difficulty would be found at the curves, and, possibly, at the transition gradients. The curve consists of two parts, the curve proper and the transition curve. The former is set off at a radius which is a fraction of the speed, such that other things being equal the radius will vary directly with the square of the maximum speed of a given coach going round the curve. It is always possible to modify matters so that the radius may not be required to increase with the speed at this enormous rate, as, for example, by adopting a more severe rise of the outer rail so as to throw the centre of momentum of the car nearer the centre of curvature. But this practice has attained its necessary limit when the amount of radial tilting of the line has become so large that it would be positively dangerous for a coach to be run over the curve at any very much lower speed. In any case, the existing curves would have to be greatly enlarged if required to suit a higher speed. The transition curve is an evolute, which is designed to avoid the sudden and highly-dangerous shock which a coach would receive if it passed immediately from a straight run to a curve of fixed radius; and its geometrical form is such that there is a steady and gradual diminution of radius from infinity to the value of the radius proper as the coach passes on to the curve. Inasmuch as the kinetic energy of a moving body is proportional to the square of its speed, it will be seen that the amplitude of the transition curve, which will produce the same time rate of change in the momentum of the coach, will increase enormously as the maximum speed is increased. Turning next to the transition gradients, we meet with similar difficulties. These gradients are the gradual development of the track from one gradient to the next in order to prevent either the shock or the tendency to "jump the rail," which would take place if a coach passed instantaneously from one gradient to another very different one. When the speed is high, there would be the altogether incurable tendency of the coach to become derailed whenever the passage is in the opposite direction; incurable, that is to say, except by a complete resetting of the gradients. These points each indicate that in order to have any very much more rapid transit than we now have, it will be necessary to set out an entirely different system of permanent ways, and to re-design every detail of the track.

Nor must the permanent way alone be changed, for it will be necessary to alter the distribution of motion within the locomotive itself in such a way as to render high speed physically possible. From some cause or other it has been found impossible to attain a higher speed than 80 miles an hour by means of an ordinary steam locomotive. The reasons for the limit have been much discussed, but its existence is scarcely disputed by competent engineers. Some have considered the cause to lie in the rapid increase of frictional resistances with increasing speed; some have attributed it to the high-back pressure and the wire-drawing consequent upon larger piston speeds; some again have endeavoured to prove that the coefficient of friction.

Digitized by Google

between the driving wheels and the rails diminishes as the speed rises, so that a limiting speed must be attained. But the most satisfactory and complete explanation is that which was put forward in 1891 by Mr. E. L. Hill, in a Paper which he read before the students of the Institution of Civil Engineers. While admitting the importance, in a minor degree, of the reasons which we have just enumerated, Mr. Hill conclusively showed that there must of necessity be, in every reciprocating-engine locomotive, forces which it is impossible to balance, and the direct effect of which must be to periodically reduce the load on the driving wheels. So great, indeed, is the fluctuation of dead weight on either of the two driving wheels of an express locomotive that even at normal speeds the value of the adhesion falls very nearly to the simultaneous value of the tractive effort. It would require but a small addition to this normal speed to bring the value of the former quantity below that of the latter, and then, of course, the wheels would begin to slip, and further acceleration would be impossible. More than this, the state of slipping of the wheels on the rails would change the friction from statical to sliding, resulting in a drop in the numerical value of the coefficient of friction to half or less than half of its former value, according to the speed. It will, therefore, be seen that a high-speed locomotive—or one which is to draw a train at more than about 80 miles an hour—will require to be driven by machinery of a rotary type.

Turning lastly to the difficulties of a financial nature which would be encountered in working a high-speed railway system, we are brought face to face with the fact that almost on every hand the increase of speed must raise the cost per train mile, as compared with the cost of the same system running at a lower speed. The single exception to the increased cost is the turnover of the capital invested in rolling stock, for at a higher speed a coach would carry more passengers any given distance in any given time. The losses during steady running would be chiefly due to windage and rail friction, and it is probable that the power required to overcome each of these would increase as the cube of the speed; and, inasmuch as the larger part of the time of running would be spent in fairly steady running, it follows that the annual cost of power will be increased almost in this ratio. When getting up speed energy must be stored in the moving coaches, and this is wholly wasted in the brakes. Since the amount of this energy is proportional to the square of the speed, and since the number of stoppages per annum will vary directly with the average speed of running, it follows that in this particular also the energy consumption varies as the cube of the rapidity of transit. Considering a concrete case, these facts imply that to run a given railway system at 100 miles an hour would cost nearly five times as much as to run the same system at 60 miles an hour. It is doubtful if many folk would be willing to pay the two-third power of fivepence per third-class mile, instead of a penny, in order to get over it more quickly; indeed, Max O'Rell tells of a Scotchman who rejoiced at having to travel in a slow train because of getting "more for his money."

To these criticisms we may anticipate that the advocates of rapid transit will raise the objection that the coefficients of resistance of the high-speed coaches they propose to build will be very much lower than those of existing railway coaches; and that, although it may be quite true the consumption of power varies with the cube of the speed, the use of a very much lower coefficient, by suitable design of the coaches, will bring down the cost to less than it is at present. Granted without hesitation that the adoption of a form of coach with smooth sides and pointed ends will bring down the coefficient of resistance to a very low figure. But if it will bring it down for high speeds it will also and equally reduce it for low ones. If it is possible to produce an efficient coach for transit at high speeds it is much more easy to produce one for low speeds. Yet, where is it? Our railway companies, with all their years of experience, have not been able to combine safety and convenience with any greatly reduced coefficient of resistance. If rapid transit engineers know of a comfortable and commodious design of railway carriage which has a coefficient of resistance less than one-fifth of that of existing railway coaches, let them produce it and run it at existing speeds on existing railways. There is a fortune awaiting them if they can.

THE PRACTICAL MEASUREMENT OF ALTERNATING ELECTRIC CURRENTS.

BY PROF. J. A. FLEMING, F.R.S.*

(Continued from page 451.)

II.—*The Measurement of Alternating Current Pressure.*

Before proceeding to discuss the various types of practical instruments for measuring alternating current pressure, it is necessary to pay attention for one moment to a distinction between electric circuits. I shall have to employ frequently the phrases inductive and non-inductive circuits, and I wish you to be perfectly clear as to the exact meaning of these terms.

Every electric conductor has the property of producing a dissipation of energy when an electric current is passed through it, and it has also the property, as a natural consequence of the above fact, of producing a fall in pressure in the current passing through it. If we consider for one moment a continuous current flowing through a conductor, then if by suitable means we measure the potential at both ends of this conductor, we find there is a fall in potential, or, as it is called, a drop in pressure down the conductor. The number by which we must multiply the strength of the current in amperes to obtain the fall in pressure measured in volts is the numerical measure of the resistance of that conductor measured in ohms. The rate at which energy is being dissipated in that conductor is numerically measured in watts by the product of this resistance and the square of the strength of the current. So far, all is simple when we are dealing with unvarying currents. If, however, we are using alternating currents then we should not find that the product of the resistance of the circuit and the $\sqrt{\text{mean-square}}$ value of the current gave us always the $\sqrt{\text{mean-square}}$ value of the drop in volts, neither would it be always true that the product of the resistance of the circuit and the mean-square value of the current would give us the mean value of the power taken up in that circuit. In other words, the drop in volts which would actually be observed in the case of an alternating-current circuit, especially if it is a circuit wrapped round iron, is more than can be accounted for by the simple resistance of the wire. We find we have in this case to take into account another quality of the circuit, which is called its self-induction. In the case of such a circuit the number by which we have to multiply the $\sqrt{\text{mean-square}}$ value of the current to obtain the $\sqrt{\text{mean-square}}$ value of the E.M.F. is the measure of what is called the impedance of that circuit. We can always measure the resistance of a circuit by means of a Wheatstone's bridge, and if taking any circuit we find that when an alternating current is passed through it the ratio of the $\sqrt{\text{mean-square}}$ value of the drop in volts down that circuit, to the $\sqrt{\text{mean-square}}$ value of the alternating current flowing in that circuit is greater than the true resistance of that circuit, such a circuit is called an inductive circuit, and the above ratio is a numerical measure of its impedance. I can best illustrate this by an example. Two wires, one of platinoid and the other of manganese steel, were wound into spirals round a wooden frame. Each of these wires was about 25ft. long, and made 40 turns round the frame. In the first place a continuous current was passed through each wire, and the fall in volts down each wire carefully measured, the magnitude of the current in both wires being 0·802 of an ampere. The drop in volts down the platinoid coil was 67·9, and down the manganese coil 79·7 volts. Accordingly the ratio of volts to currents in the first place is 84·66, and in the second case 99·38. This being done, an alternating current of the same $\sqrt{\text{mean-square}}$ value, as measured by a Kelvin balance, was passed through the two coils. The fall in volts down the platinoid coil was found to be 68·5, and down the manganese steel coil 80·7. These were the mean-square values. The ratio of volts to current in the first case is, therefore 85·41, and in the second case 100. These, therefore, are the impedances of these coils, and it is seen that in each case the impedance exceeds the resistance. The frequency of this alternating current was 108, and therefore these coils form slightly inductive circuits. I shall point out presently the manner in which practically non-inductive circuits may be obtained; but meanwhile it is sufficient to remark that if an iron core had been inserted in either of these coils, it would have greatly increased the impedance of that coil. It is always possible, however, to ascertain whether the impedance of a circuit differs from its resistance in numerical value. If it does not to any sensible extent, then the circuit is called a non-inductive circuit. If the impedance is greater than the resistance then the circuit is called an inductive circuit. There are many cases in which inductive circuits cannot be employed, but in which we must secure, by some means or other, a practically non-inductive circuit. Such a non-inductive circuit can be formed of a series of incandescent lamps, and for larger currents it can most conve-

* Abstract of Cantor Lecture delivered before the Society of Arts.

Digitized by Google

niently be obtained by using rods formed of a mixture of plumbago and fire-clay, mixed in proper proportions to secure the necessary resistance, and then baked.

Turning now to the question of the measurement of alternating-current pressure, we will consider the various types of instruments which can be used for this purpose. In the first place, any one of the class of electro-dynamometer instruments or electro-magnetic instruments described in my last lecture, which can be wound with very fine wire, so as to make a current-measuring instrument of high resistance, can thereby become an instrument for the comparison of alternating-current pressure, provided that certain precautions are employed. In the first place, we may make a high-resistance dynamometer by winding a dynamometer with a wire of high specific resistance and of necessary length. The impedance of this instrument is, therefore, a fixed quantity, provided that we are dealing always with alternate currents of the same frequency. The indications of the instrument are indicative of $\sqrt{\text{mean-square}}$ value of the current flowing through it; and hence, by what has been above said, as to the definition of impedance, it follows that the $\sqrt{\text{mean-square}}$ value of the alternating-current pressure at the terminals of the instrument will also be given by the instrumental reading. In other words, we can take such a high-resistance dynamometer, and can graduate it for alternating pressure to any given frequency; but if the dynamometer has an impedance which differs sensibly from its true resistance, then, if calibrated for alternating currents of one frequency, it will not, in general, be identical in its indications for alternating currents of different frequency. We can, however, nearly always secure the condition that the impedance of such an instrument shall differ by very little from its true resistance, and then, when once it has been calibrated, by testing it with known unvarying pressures, it will enable us to measure alternating-current pressures, giving us their $\sqrt{\text{mean-square}}$ values.

In order to obtain the necessary non-inductive quality in such an instrument it is generally necessary to place the greater part of the resistance of the instrument in the form of a non-inductive coil of platinoid wire, which is placed outside the instrument, and then to a considerable extent we may be sacrificing sensibility. The same statements are true with regard to the employment of the electro-magnetic principle in the construction of alternating-current voltmeters. In all the instruments described in my former lecture Siemens dynamometers, the alternating-current ammeters made by Nalder, Evershed, Elihu Thomson, and Dobrowolsky, can be converted into alternating current voltmeters by winding them with very high resistance wires, putting that resistance in the form of a non-inductive resistance associated with the measuring part. In Evershed's current volt-ammeter there is a compensation for frequency which is worth noting. The voltmeter coil has placed in series with it a coil, the terminals of which are shunted by a condenser. This shunted condenser has the property of neutralising the self-induction of the voltmeter coil, and if properly adjusted, the instrument may be made to give identical scale indications for alternating pressures of widely different frequencies, and be practically compensated for frequency.

Turning, then, to the instruments for the measurement of alternating electromotive forces in which the thermal principle is employed, we have, first, the well-known Cardew voltmeter as a typical instrument for the measurement of such alternating pressures. In this instrument a platinum silver wire, of about 300 ohms resistance, is stretched in a tube, and, for the sake of compactness, the wire is folded backwards and forwards four times over small ivory pulleys. One end of this wire is fixed, and when a current is sent through the wire it becomes heated, and it attains a final temperature if the current passing through it is constant. The wire, therefore, elongates, and the expansion of the wire is measured and detected by a multiplying gear of the following kind. The elongation of the wire is made to cause a revolution of a mechanism consisting of an intergear of wheels and pinions, and to the last axis of the series an indicating needle is attached, moving over a divided dial. The wire has to be held in a tube or frame, and there are two types of this instrument, called respectively the rod and the tube type. In the rod type of instrument, which is the easiest to manufacture, the platinum-silver wire is kept extended by being fastened to two rods, formed one-third of iron and two-thirds of brass. The whole instrument is then enclosed in a brass case. When the current is passed through the wire it heats it, and the rods become heated also by radiation from the wire. It takes a certain time before the rods settle down into a final state of temperature, in which the heat received by them is equal to the heat radiated by them. Until this is the case, the instrument does not come to its final reading. In the other type of instrument, called the tube instrument, the wire is attached simply to the brass and iron tube, which forms the case of the instrument. In this latter type the outside tube arrives very much more quickly at its final state of temperature, and hence the instruments of the tube type are preferable for accurate work on account of the fact that they thus come much more quickly to their final readings when put upon the circuits. The Edison-Swan Company manufacture a type of Cardew voltmeter which is easier to string than the ordinary tube instrument, and yet has all the advantages of that instrument. Another disadvantage which the rod instrument possesses is that there is generally a considerable negative variation of the needle on taking off the current. The rods do not cool as quickly as the wire, and, therefore, when the current is taken off, the needle goes back beyond the zero of the scale. The instruments are generally made for reading pressures from 40 to 150 volts. In the manufacture of the instruments the wire has first to be carefully aged by putting current on and off for some time at intervals of one minute, so as to heat and cool the wire. In this way a certain variation in expansion is got rid of, and the platinum-silver wire is brought into a condition in which it always is the same length and the same temperature. These Cardew voltmeters are really of course alternating current ammeters which take a current of about one-third of an ampere at 100 volts. The instrument of this range therefore dissipates a power of 30 watts, and, as I shall point out later on, has the disadvantage of wasting a considerable amount of energy if kept continuously upon the circuit, but when carefully made the Cardew voltmeter is an instrument of great value for measuring alternating current pressure. A special form

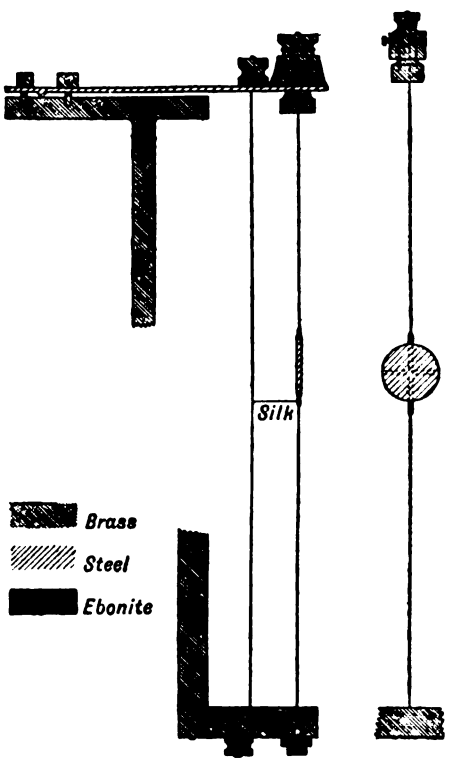

FIG. 9.

of this Cardew voltmeter is also made by the Edison-Swan Company for engine-room purposes, the dial of which is very large, and which is graduated say from 80 to 110 volts. In this way such a graduation is given to the instrument that a variation of one volt can be easily seen at a considerable distance. There are some modifications of the Cardew voltmeter which are useful in measuring very small alternating E.M.F., such as the voltmeter of Major Holden. In this instrument a short and very fine platinum silver wire is stretched between two supports, and it is kept sagged in the middle by means of a small spring (*see* Fig. 9). To the centre of the wire is attached a thread, also attached at the other end to the side of a small mirror. If the sag of the wire increases or diminishes, the mirror is more or less pulled round. When a current is passed through the wire it heats it. The sag increases and the mirror is moved. This instrument will measure without an external resistance from nothing up to two volts conveniently, and by putting the external resistance in series with it, and by employing a long ray of light the instrument can be made to indicate pressures of any required voltage with great accuracy. Major Holden has converted the above-described instrument into a useful self-registering voltmeter making a photographic record of variation in pressure. This is achieved by letting the ray of light reflected from the mirror fall upon a revolving drum covered with photographic paper. The drum turns round by clockwork once in 24 hours, and the ray of light marks a photographic record of the revolving paper by which any variation in the pressure is detected and measured. A similar low voltage thermal

Digitized by Google

voltmeter is constructed for use with secondary batteries for measuring the E.M.F. of each cell. In using such thermal voltmeters it is necessary to avoid convection currents of air in the enclosing tube or case. In using a Cardew voltmeter it is generally found best to place the instrument with the tube horizontal. In this way the variable cooling effects of the air currents in the tube are, to some extent, prevented. If a Cardew voltmeter is used with its tube vertical, the needle will be observed to make small movements to and fro, even if the current is perfectly steady. These movements of the needle may, if they occur, prevent the pressure from being accurately read within less than one volt.

We must now pass on to notice instruments for the measurement of alternating pressure which depend upon electrostatic attractions. These electrostatic instruments have for many purposes very great advantages, the most notable of which is that they do not consume power, and that, therefore, they may be left on the circuits indefinitely without cost. The first of these instruments which I will describe is Lord Kelvin's electrostatic voltmeter for high pressures. It consists of four quadrant-shaped plates which are connected to one terminal of the instrument. Suspended between these plates, but insulated from them, is a paddle-shaped aluminium needle, which swings on very delicate pivots. The needle is connected to the other terminal of the instrument. The instrument, in fact, forms a condenser, of which one plate is fixed and the other is movable. When a difference of potential, varying from 1,000 to 5,000 volts, is produced between the terminals of the instrument, the movable plate is attracted in between the fixed plates. This movement is resisted by weights, which are hung on the bottom of the needle. When two plates, in fixed positions, have produced between them a difference of potential, the force required to hold them in any given position is proportional to the square of the difference of potential between them. To the end of the aluminium needle is attached a long pointer, moving over a divided scale, and the instrument is graduated in such a manner as to read directly in volts. Since the attraction between the plates depends upon the square of the potential difference, it is independent of sign, and therefore the instrument works equally well with direct or alternating pressures; and, in this latter case, it gives us the $\sqrt{\text{mean-square}}$ value of the potential difference between the terminals of the instrument.

Another instrument, also invented by Lord Kelvin, but adapted for measuring lower pressures, is the multicellular electrostatic voltmeter. In this instrument there are a series of quadrant shaped plates placed one above the other, which are called cells. There are then a series of paddle-shaped needles, all attached to a common axis, which is hung up by a platinum silver wire. The normal position of the needles is just outside the quadrants, but if a difference of potential is created between the needles and the cells, and the needle is drawn or attracted into the cells, this movement is resisted by the torsion of the suspending wire. An indicating needle, attached to the axis, moves over a divided scale; and the instrument, which can be arranged to measure from 40 volts upwards, gives us, therefore, the $\sqrt{\text{mean-square}}$ value of the potential difference between the cells and the needle.

In these instruments there may be a very small error in reading, which is dependent upon the existence of a small E.M.F. of contact between different metals. If the cells are made of brass and the needle of aluminium, there is a small contact difference of potential, which is due to these different metals, and which may amount to something less than half a volt. Accordingly, it will be found that in such an instrument, reading, say, 100 volts, the reading given by the instrument will depend upon whether the cells are positive or negative, and a small correction has to be applied, depending on the manner in which the instrument has been joined up in calibrating it. Similar instruments for measuring potential differences of much larger amount have been invented by Lord Kelvin. In these instruments the electrostatic attractions between two plates are balanced by the gravity of a weight. One of the plates is a fixed insulated plate, and the other a movable plate hung on a balance arm. The movement of a needle over a scale indicates the pressure in volts. Instruments similar in principle to the above have been devised both by Prof. Ayrton and Mr. Swinburne. In both these instruments the same principle is employed. There is a fixed insulated plate, and a movable plate to which is attached a needle. The electrostatic attractions between these plates are made to move the needle over a divided scale. Lord Kelvin has also devised a form of multicellular voltmeter which is useful for central-station purposes as it has a vertical scale, and the instrument is intended to be attached to a switchboard. I may now point out the advantage of these electrostatic instruments to which I referred a moment ago. Take, for instance, a thermal voltmeter absorbing 30 watts, and assume that this instrument is kept connected to the circuits in the dynamo room of a central station all the year round. Since there are, roughly, 8,000 hours in a year, this instrument, absorbing 30 watts, would in one year dissipate 240 Board of Trade units of electric energy. If we reckon this energy as costing 1d. per unit, it is evident that this instrument will cost 240d., or £1 per annum, to keep it going. In reading alternate-current pressures higher than 100 volts, a transformer has to be interposed between the circuits and the voltmeter, to reduce the pressure. This transformer will also use up energy, and if it takes no more than the voltmeter, it will also waste £1's worth of electric energy in the course of a year. We see, therefore, that an electrostatic instrument which wastes no energy at all is, in cost of up-keep, much superior to the electro-thermal or the electro-magnetic type of instrument; and, in fact, we can afford to spend a great deal more on an electrostatic instrument, and yet effect a total saving in the cost of the electric measurements in that station. For suppose we capitalise our £1 at 10 per cent., we can then afford to spend £10 more on an instrument of the electrostatic type than one of the electro-thermal or the electro-magnetic type, which wastes no more than 30 watts if we keep them on the circuits always. There is, therefore, every reason to believe that in course of time electrostatic instruments for the measurement of pressure will entirely supersede instruments of the electro-thermal or electro-magnetic type in all those cases in which the instruments have to be kept upon the circuits constantly. We may employ these electrostatic voltmeters for the measurement of alternating currents, and convert them into alternating-current ammeters in the following way. Let a non-inductive resistance, say of platinoid wire, be constructed which is capable of passing without sensibly heating the current to be measured, and let the resistance of this wire be accurately known. Then to the ends of this circuit attach an electrostatic voltmeter. Knowing the difference of pressure between the ends of the resistance and its resistance, we know the current flowing through it. In many cases, as in measuring the primary currents of a transformer at no load, it is much more convenient to employ such an electrostatic voltmeter and non-inductive resistance than any other method. Suitable non-inductive resistance can always be made by coils of platinoid wire, joined in parallel; and these must be so adjusted that the final temperature they attain is not more than a few degrees above the normal temperature.

(To be continued.)

ON THE ELECTRIC LIGHT OF LIGHTHOUSES.*

BY ANDRÉ BLONDEL.

With the object of improving, if possible, its installations, the Lighthouse Department of France has undertaken, on the initiative and under the direction of M. Bourdelles, Inspector-General, since 1891 a series of systematic experiments, which have had reference to the use of both continuous and alternate currents. The results have already been summarised in the notice on lighthouse apparatus presented by this Department to the Chicago Exhibition. I propose here to explain in more detail the investigations that have been made with the two varieties of current at the lighthouse establishment, and at the same time the considerations that weigh in favour of each solution.

In a certain number of old lighthouses two grades only are used—a single and a double light—one, as the term implies, corresponding to double the intensity of current of the other. In French lighthouses of the old type these intensities are respectively 50 and 100 amperes. In the English lighthouse of St. Catherine they are 175 and 350 amperes, They are obtained by supplying the lamp either with one of De Méritens' machines, type G or L, or with two coupled in parallel circuit. But the gradation so obtained is imperfect, because the reduction of range due to atmospheric absorption varies in a much greater ratio than that of 2 to 1, when the weather changes from moderately clear to foggy. In average weather—that is to say, for about 20 per cent. of the year—on the French coast of the Channel and the ocean, a current of 25 amperes is more than sufficient, with bifocal apparatus, to enable the geographical range to be attained, and even surpassed. In the flashing apparatus, "feux-éclairs," an illumination is realised which reaches to 85 miles, whilst in foggy weather a double intensity corresponding to a current of 100 amperes only reaches 26 miles. In these conditions it is necessary that the intensity of the current should vary at least from 1 to 4, and that the weaker currents, which are the most used, should be obtained with suitable efficiency. In French lighthouses the two extreme currents are 25 and 100 amperes. Many combinations may be made to obtain intermediate gradations.

Arc lamps, as we know, have their mechanism in the lower part, and rest directly on the platform (Fig. 1), of the optical apparatus. Their principal function is to constantly bring together the carbons as they are consumed. Some of them have a striking arrangement which automatically separates the carbons to start the arc. But none of them in ordinary working can increase the distance of the carbons if they have accidentally come too close to each other. In

* Abstract of a Paper read at the International Maritime Congress, London meeting.

Digitized by Google

that respect an improvement might, perhaps, be introduced, but we can avoid the cause of too near an approach by suppressing, as we shall see later, the variations of the current.

The lamps for alternate currents (Fig 1), almost the only ones at present used, all belong to the original Serrin type, or to that type modified in certain points of detail by MM. Berjot, Le Baron, Ciolina, &c. The movement of approach, which is made under the action of the weight of the upper carbon-holder, is governed by clockwork, with an escapement put in play by an electro-magnet when the distance becomes too great.

The necessity of reducing the heating effect on the magnet and the change of attractive force that arises with the change of current has led for some time to the abandonment of the practice of putting the electro-magnet in series with the principal current. In the new French lighthouses we send, whatever the main current may be, the current of half of one of the machines of De Méritens through the electro-magnet; the remainder goes directly to the lower carbon by another cable. This method, which requires three cables, complicates the installation and the construction of the switch-board, although care may be taken to connect all the commutators of this board so as to enable the change of current to be made by one operation. It is more natural to employ, as in the lamps of Le Baron, an electro-magnet placed in a shunt and wound with fine wire. The number of conductors is reduced to two, and there is no further need to split up the machine circuit.

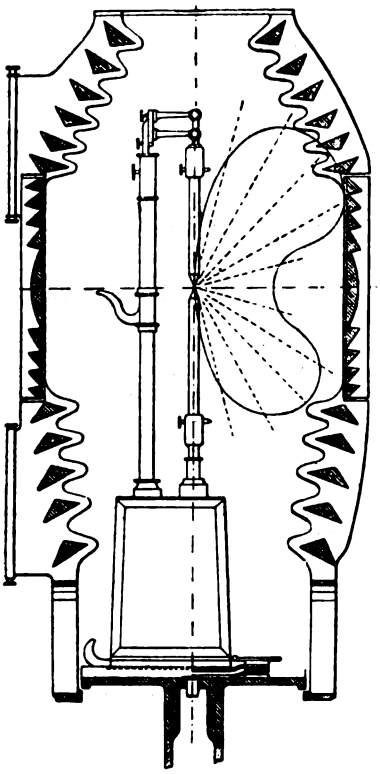

Fig. 1.

The same type of regulator might also well be applied to continuous currents. Messrs. Sautter and Harlé have preferred to adopt for the experimental lamps of the lighthouse of La Hève a type analogous to that of the projectors (Fig. 2), in which the approach of the carbons is produced by a screw passing through the two carbon-holders, and operated by an electromotor through a rachet. The latter receives a shunt from the principal current through a relay controlled by a small electro-magnet placed in shunt across the terminals of the lamp. Each movement of the screw is accompanied by a similar movement of rotation of the socket of the lower carbon-holder so as to regulate the shape of the carbons. But this movement is too slow to produce a favourable result. The principal advantage of this lamp consists in the employment of a solenoid placed around the lower carbon, of which the purpose will be later explained. With the present lamps the regulation of the arc so that it may occupy the focus of the apparatus is effected, as is well-known, by the aid of a screw that raises or lowers the two carbons simultaneously. The attendant constantly moves this screw so as to bring the image of the arc or of one of the carbons to a mark traced on the table. There would evidently be an advantage in producing this movement automatically, but the attempts made in this direction have not been sufficiently satisfactory to lead us to pursue them further. An automatic system would also have the disadvantage of not requiring the attention of the attendant, which it is as well to stimulate.

It appears to be established that the arc consists of a current of carbon reduced to a state of vapour at the surface of the positive pole, which assumes the form of a crater; owing to this circumstance the positive pole constitutes the most brilliant part of the electric arc. It is estimated that it furnishes more than 85 per cent. of the light produced, while the negative carbon give less than 10 per cent., and the arc, properly so-called, less than 5 per cent. The temperature of volatilisation of carbon being a physical constant, the temperature of the crater must be invariable for a given carbon, and consequently also its intrinsic brightness (that is to say, per unit of surface). The experiments of Messrs. Abney, Rosetti, and Violle, &c., have shown that this is correct. But this law is only applicable to the maximum brightness; in fact, this maximum is only produced on a variable portion of the crater, and the mean brightness of the crater may vary within wide limits (that is to say, the total light that it emits divided by its total surface). In the experiments made in 1878 at Chatham by Royal Engineer officers it was found that the mean brightness may vary from 26,000 to 76,000 candles per square inch. I have also observed similar variations.

Distribution of the Light.—The power of a pencil of light produced by a luminous source placed in a given apparatus only depends, as we know, on its mean brightness and the geometrical form of the apparatus, and on the surface of the latter usefully illuminated. In the present case the useful parts are those which receive the light of the crater. The well-known form of the curve of distribution of the arc light from continuous currents (Fig. 3) shows the unsymmetrical fashion in which this light is distributed; and Mr. Trotter has recently proved that in every direction the quantity received is nearly proportional to the portion of the visible surface of the crater. It thus appears that above the horizontal plane through the edges of the crater the electric arc is of no great service.

Arrangement of the Carbons.—In placing in our present apparatus the positive carbon above the negative, as was done in the

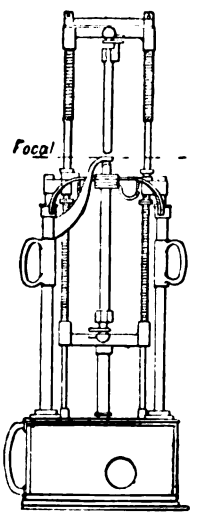

Fig. 2.

first applications, notably at the Lizard (England), the most important part of the apparatus was not made use of. Sir James Douglass proposed, in order to overcome this difficulty, to place one of the carbons eccentrically, so as to produce an oblique crater similar to that of projectors. But this arrangement, which only illuminates the apparatus over a very limited part, is unsuitable for lighthouses in the generality of cases. It has, then, been attempted to place the positive carbon below and the negative above, but a further difficulty is then met with. The arc which with the crater above finds itself, so to speak, kept in place by the latter, now begins to travel round the edges, is uncertain, and is easily extinguished. This difficulty, not important with small lamps, becomes so serious with currents of more than 50 amperes, that it has hitherto completely hindered the employment of continuous currents. An attempt made in this direction at May Island (Scotland) in 1886 proved disappointing.

Messrs. Sautter, Harlé and Co. have recently overcome the difficulty by a very ingenious application of electro-dynamic action; for this purpose they arranged concentrically to the lower carbon (Fig. 2), and as near as possible to the arc, a solenoid formed of several turns of thick copper wire traversed by a shunt from the current of the lamp and protected by a refractory plate; the arc, behaving like a fluid conducting body, begins to turn around its own axis with a very rapid movement, as was shown by an instantaneous photographic record, and immediately obtains, in virtue of its gyration, a great stability. The regularity

Digitized by Google

in the shape of the carbons is favoured in some measure by the slow movement of rotation given as described above to the lower carbon. It is with a Sautter-Harlé lamp of this system that the experiments have been made at the lighthouse establishment, and will be pursued at the lighthouse of La Hève. It might be well to adopt it for continuous currents, if we had to preserve the present forms of lamps and apparatus. In this case all the part of the optical apparatus below the focal plane not seeing the crater ought to have as its focus the point of the negative carbon. It would even be better to suppress it completely, and give to the cupola a larger development in diameter and in height, as was done for the apparatus of the Isle of May, where the only thing objectionable was in replacing by catadioptric rings the upper half of the dioptric drum. Under these circumstances it might perhaps be advantageous in certain respects to turn round the half apparatus, giving it the arrangement shown by Fig. 3. We might then replace the ordinary lamp by a lamp suspended to the upper part and analogous, save as regards power, to those employed in public lighting, in adopting for carrying the lower carbon a single rod placed on the land side,

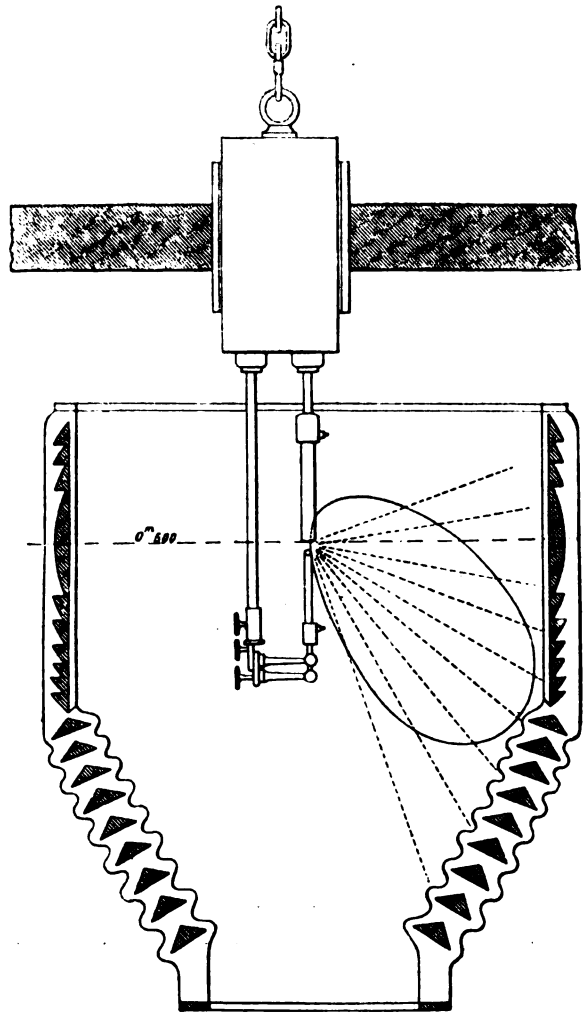

FIG. 3.

the lamp might be put in a case fixed to a small footbridge accessible to the attendant, and its replacing could be effected almost instantaneously, without any need of stopping the apparatus of rotation. Thanks to the employment of a positive carbon above, we should obtain a suitable condition of the arc more easily than now. Lastly, in giving to the apparatus a diameter of 1 metre in place of 0·60 metre, for example, we should amply compensate for the loss of useful surface due to the suppression of a part of the drum and of the ring, and should restore the horizontal divergence to a value nearly that which it has at present.

Useful Effect Obtained with Different Currents.—With arcs which are geometrically similar (that is to say, in which the proportion between the distance apart of the carbons, the diameter of the carbons, and the square root of the intensity remains the same), the occultations of the crater by the negative carbon have the same relative value. We must, then, always obtain the same optical effect at a great distance, and there would be no advantage in employing arcs of great intensity. In practice this somewhat hasty conclusion is contradicted by experience, as is shown by the following table, in which are collected results obtained from experiments made with similar continuous-current arcs :—

Apparatus.	Diameter of carbons. Upper	Diameter of carbons. Lower	Intensity of current in amperes.	Pressure at the terminus in volts.	Power expended in watts.	Mean minimum power in carcels (carcel = 10 c.p.).	Luminous efficiency per watt in carcels.
	mms.	mms.					
Bifocal (type, 1888)	10	13	25	50	1,250	411·	·329
,,	18	22	75	53	3,975	661·8	·167
,,	18	25	90	52	4,680	900·	·192
Feu-éclair bifocal apparatus of La Hève	13	13	25	53	1,325	637·	·481
,,	18	21	47	55	2,585	916·	·354
,,	21	23	98	50	4,900	1,300·	·265
,,	18	23	94	57	5,358	1,781·	·332

This apparent contradiction might be explained by the small extent of the luminous surface compared to the inevitable aberrations. Further, we must not forget that when the maximum brightness is constant the mean brightness of the useful incandescent part may be variable within certain limits, as was said above.

Separation of the Carbons.—The minimum distance apart which enables us to obtain from arcs of 25 amperes and upwards a light free from hissing is from 4mm. to 5mm., corresponding to a pressure of 45 volts at the arc and about 50 volts at the lamp terminals. There is an advantage with regard to optical efficiency in increasing the distance a little until the crater is completely free without passing the limit at which the arc becomes unstable and produces too much flame.

Properties and Effects of the Alternate-Current Arc.—The arc produced by alternate currents results from a transport of carbon, no longer continuous and constant, but variable and alternate.* At the same time that the direction of the current changes, the arc is extinguished in a more or less gradual manner.† This extinction is not perceptible to the eye above a frequency of 40 per second; but, below this value, it produces a barely perceptible twinkling. As it is difficult to obtain alternators of small power and of slow speed giving a high frequency, we should be content with a frequency not much larger than this minimum. It will be seen later that no inconvenience arises from this in respect of the intrinsic brightness.

To produce an alternate-current arc with a frequency of 50, the minimum pressure of about 25 volts need only be attained or surpassed during a fraction of the alternation of something like half; the average pressure is then lower than that for the continuous current arc. A lighthouse arc requires, length and intensity being equal, an alternate current of 45 volts instead of a continuous current of 50 to 55.

The true power (P) expended in an alternate-current arc is always less than the apparent power (E I). The ratio of these two quantities, according to numerous measurements which I have made with the help of the wattmeter, or by means of the periodic curves, stands on an average at the following figures for arcs whose frequency is 50 :—

Arc.	Coefficient of power, $\frac{P}{E I}$.
Steady and silent	0·90 to 0·95
Noisy and unsteady (with a separation of 2 to 5 millimetres)	0·85 to 0·90
Hissing and striking.....	0·75 to 0·80

Conditions of Steadiness.—The steadiness of the alternate-current arc requires, in addition, that the available electromotive force employed should be sensibly superior to the difference of potential at the terminals, either because the arc behaves during each infinitely small period of time just like a continuous-current arc, or because after each extinction an increased pressure is necessary to relight the arc. Numerous experiments have shown that for a lighthouse arc of 25 amperes and 45 volts with hard carbons, such as those described later on, it is necessary to have at command an induced electromotive force of at least 60 volts.

* In the first "Alliance" machines the currents were rectified by the aid of a commutator; the arc was not then alternate, but simply intermittent.

† A complete study of these phenomena will be found in two other works—*Lumière Électrique*, Vol. XLII., December, 1891; Vol. XLIII., January, 1892, &c.

Digitized by Google

In order to bring back the pressure at the terminals of the lamp to 45 volts a resistance is no longer interpolated, but self-induction, which, while giving more elasticity to the arc, does not absorb energy. This being so, there is nothing to prevent the employment of an electromotive force of 75 to 85 volts, and obtaining by this means exceptionally steady arcs, which relight of themselves when they are blown out or extinguished.

Distribution of the Light.—Thanks to the form of the points of the carbons, the light can be directed almost equally to all parts of the lenses in contradistinction to what occurs in the case of continuous currents. The form of the curve of light distribution given by M. Allard* is only applicable to arcs of very small length. It would probably be suitable to the arc light of St. Catherine (Isle of Wight), the separation in which is not more than $\frac{1}{2}$mm., and the pressure only from 35 to 38 volts. With an arc so short, almost always on the point of sticking together, the surfaces of maximum brightness are almost completely shaded by the carbons, and it seems hard to believe that the highest efficiency could be realised in this way, as some have asserted.

In France it is preferred to employ a genuine arc, with a pressure of 45 volts, corresponding to a separation of 4 to 5 mm. for the current of 25 amperes, and exposing the bright surfaces. The part played as a lightning agent by these is then shown by the curve of light-distribution, which assumes the appearance of a butterfly (Fig. 1), giving maxima in directions having an inclination of 45deg., the superiority of which over the horizontal intensity becomes more marked as the separation is made greater.

Intrinsic Brightness.—It would seem that the maximum intrinsic brightness ought to be less than in the case of the continuous-current arc, since each surface only acts as a positive pole during one alternation in every two, and even less, and can thus cool during the remainder of each period. As a matter of fact, this is the case with arcs of very small intensity (8 to 10 amperes). But in those of 25 amperes and upwards, the period of extinction being very short, and each crater being smaller than the average intensity would require, the measurements made with the Le Chatelier pyrophotometer at a frequency of 50 have not shown any appreciable difference. The maximum brightness does not even vary to any extent with the intensity or with the separation. But the same reservations, as in the case of the continuous current, must be made as far as the average brightness is concerned.

Practical Effect with Different Currents.—To appreciate the ultimate effect in the optical apparatus, we come back, then, once more to the question of occultations. The bifocal arrangement devised by Inspector-General Bourdelles, which consists in placing the focus of the dioptric drum (Fig. 1) at the centre of the incandescent part of the lower carbon, and the focus of the catadioptric rings at the centre of the incandescent part of the upper carbon, theoretically allows of nearly all the focal rays of the apparatus passing by the surfaces of maximum brightness. But in practice this maximum efficiency is not realised, owing to inevitable occultations, and to an effect analogous to that already pointed out in the case of continuous currents. The power of the pencil still increases with the intensity of the current, as is shown by the following table, which I borrow from the paper already quoted, only adding the column of true efficiencies :—

Diameters of the carbons.	Amperes.	Volts.	Apparent watts.	True watts.	Carcels of ten candles.	Efficiency per watt.
10	25	45	1,125	1,070	1,200,000	1,120
16	50	45	2,250	2,140	1,800,000	840
25	100	45	4,500	4,275	2,300,000	512

The explanation of this phenomenon might be sought in the same causes as in the case of continuous currents. However that may be, as the luminous power only increases slightly in comparison to the expenditure of energy, there could be no advantage in going further in this direction, and it would be preferable, in accordance with the curious observation of M. Bourdelles, to unite several lights of small intensity in separate lenses.

However, if we have to employ later on lenses of greater diameters (3rd, 2nd, and 1st order), the period of brightness being less than the maximum time of perception, all the light would be utilised; and even admitting that the brightness would remain the same, there would be an advantage in increasing, within certain limits, the power of the arc.

Choice of Carbons, Diameter, and Separation.—For the same reason as with continuous currents, we employ the hardest possible carbons. The specific resistance of "Carré" carbons, which give excellent results, increases with the diameter; it may be estimated on an average at 7,000 to 8,000 microhms. The smallest admissible dimensions, and consequently the most satisfactory, are indicated in the preceding Table. They correspond to currents of 0·315, 0·25, and 0·24 amperes per square millimetre.

This current density might be further increased, and consequently the diameter diminished, by the employment of carbons lightly coated with copper ($\frac{1}{10}$th of a millimetre), so that the melting of the copper may not produce any accidental shunt circuit, followed by extinction.

The arc cannot be made longer than 10 to 15 millimetres without producing a large flame. Geometrically it appears sufficient to separate the parts raised to the maximum brightness until the distance is equal to half the diameter of the terminal faces, or about a quarter the diameter of the carbons, that is to say, to 6 millimetres for arcs of 100 amperes. The two foci of bifocal lenses being at 1cm. apart, we are thus assured that the focal rays pass through the incandescent portions. The corresponding pressure, which is about 45 volts, has been allowed for all the currents in order not to complicate the service whilst realising the maximum power of the De Méritens machines at the speed of 550 revolutions. To determine directly the best distance between the carbons, a series of experiments should be made with the same intensity of current. The measurements made on this point at the Lighthouse Department (France) have only availed to establish that in bifocal lenses, and with magneto machines, the actual currents were higher than those that would be obtained by increasing the separation, as the following table shows :—

Diameter of the carbons.	Distance apart.	Intensity.	Pressure.	Electric power.		Luminous power.	Efficiency per watt.
				Apparent.	Corrected.		
mm.	mm.	amperes.	volts.				
16	5	50	45	2,250	2,140	1,925,000	900
16	15	45	50	2,250	2,140	1,140,000	532
10	4	25	45	1,125	1,069	1,110,000	1,032
10	6	23	47	1,080	1,026	1,014,000	980
10	8	19	52	988	939	720,000	771

But these conclusions would not necessarily apply to different types of machine or optical apparatus.

Comparison of Continuous and Alternate Currents.

This comparison, the elements for which have been furnished in the preceding chapters, should refer at once to the arc, the optical apparatus, and the dynamos.

1. *The Dynamos.*—The continuous current dynamos are satisfactory from the point of view of strength and safety. They show great economy in space and in cost compared to the De Méritens machines, but the steadiness of the arc has only been obtained at the cost of a loss of efficiency, the efficiency at the terminals of the lamp having been reduced to 0·58 or 0·65 at the 25 and 50 ampere currents.* On the contrary, the new alternators allow us to preserve the advantages of the De Méritens machines while costing a little more than the dynamos, and giving electrical efficiencies of 74 and 80 per cent. at the two currents considered. It is these machines, then, which appear at present likely to take the place of the De Méritens machines without any change in the remainder of the service.

But it is not to be forgotten that all the possible advantage obtainable from continuous current dynamos has not yet been obtained, and that by a suitable compounding we might probably realise a stability and efficiency superior to those hitherto obtained with these machines.

2. *The Arc.*—In spite of the ingenious solenoid of MM. Sautter, Harlé and Co., and the employment of the rheostat, the continuous current with the positive carbon below remains inferior in regularity to the alternate current arc. This may be seen from the following table, which sums up in a comparison the variations in illumination of the ray observed in the experiment of the central depot.

Variations in Arc Lights.

Apparatus.	Current.	Relative variations of the luminous power.		
		With current of 25 amperes.	With current of 30 amperes.	With current of 100 amperes.
Feu-éclair type, 1892	Alternate	Per cent. 30 to 36	Per cent. 40 to 50	Per cent. 50 to 70
Ditto	Continuous	142	165	187

* It is just to observe, nevertheless, that at the lighthouse of La Hève, where the definitive experiments will take place, the steadying resistances may be suppressed in large measure owing to the resistance of the cables.

* "Memoire sur les Phares Électriques," Plate I., Fig. 4.

Digitized by Google

This inferiority is especially important with feux-éclairs, in which the lamp turns with the apparatus, and where it is consequently necessary that the figure should be as symmetrical as possible in order that successive flashes may be of equal power. The arc with positive carbon uppermost would give in this respect more favourable results.

3. *Apparatus.*—The present bifocal apparatus is combined for the use of the alternate current. Experiments made at La Hève (feu-éclair) with an apparatus of 0·60 metre in diameter, in four panels, have given, with almost equal currents, luminous powers and efficiencies much superior with alternate currents to those obtained with continuous currents, as is shown by the following table* :—

Intensity of current.	Continuous currents.			Alternate currents.			Ratio of luminous powers with equal intensity.
	Volts.	Luminous power. Carcels.	Efficiency in carcels per watt.	Volts.	Luminous power. Carcels.	Efficiency in carcels per watt.	
25	53	650,000	480	45	1,200,000	1,120	1·85
50	55	1,000,000	350	45	1,800,000	840	1·80
100	50	1,300,000	265	45	2,300,000	512	1·76

These figures are, as we said above, only the mean, and not the absolute values.

4. *Efficiency.*—The preceding table gives the efficiency measured at the lamp—that is to say, the number of becs per electric watt consumed by it. To have the definite efficiency—that is to say, the number of becs per watt of mechanical power furnished to the dynamo—we must multiply these figures by the value of the efficiency of the dynamo, including the rheostat. We thus obtain the following results in the conditions realised in the respective experiments :—

Current in amperes.	Efficiency of the De Méritens magneto.	Efficiency of the Sautter-Harlé dynamo with rheostat.	Luminous efficiency. Carcels.	
			Alternate current.	Continuous current.
25	0 52	0·58	625	278
50	0·73	0·65	615	227
100	0·73	0·65	374	172

The alternate-current is superior, then, by more than 100 per cent. to the continuous current, and the advantage would have been still greater if the new alternators had been employed. But the ratio of the luminous power obtained—a ratio which shows a remarkable constancy, and which is on the average practically equal to 1·80—only represents in reality the ratio of the surfaces of the apparatus usefully illuminated in each case, that is to say, the ratio of the total surface to the portion of surface situated above the focal plane. If we calculate the value of these surfaces we find their ratio is about 1·90, which confirms this view.

To obtain with the continuous current the same power as with the alternate current, it would then suffice to increase the surface utilised in the manner indicated above ; for example, in the monofocal apparatus of 1·00 metre diameter, represented in Fig. 3, we should realise a useful surface, about 1·3 times greater than that of the apparatus of La Hève.

Conclusions.—The comparison between the two systems will only be definitive when it takes into account more improved dynamos, and optical apparatus specially suited to each. *A priori*, it is difficult to say which will give the best efficiency in the end. It would seem, however, that the alternate-current arc will always keep its superiority, because of the smaller voltage with which it is satisfied when the separation of the carbons is equal, and because of the great steadiness of working of the alternators that feed it.

With equal efficiency alternate currents offer, besides, a greater facility for distributing the light below the horizon by the use of the bifocal form, and they permit the employment of a smaller and more symmetrical apparatus than does the continuous current.

Also in view of the entirely satisfactory results furnished by alternate currents, and the remarkable advantages shown by the De Méritens machines or alternators endowed with similar properties, the French lighthouse service has not thought well to go on with the use of continuous currents at present in the new optical apparatus. This path, is, nevertheless, open to the initiative of manufacturers.*

Résumé and Conclusions.

To summarise, in this investigation I have analysed the different conditions necessary to the successful operation of an electric lighthouse with continuous or alternate currents. As to the chief *desiderata* relating to the machines, to the lamps, and to the optical apparatus in each of these two systems, and the comparative results obtained by the lighthouse service in France, the conclusions of this investigation are as follows :—

1. The three elements constituting an electric lighthouse—machine, lamp, and optical apparatus—should not be studied separately, but taken together, in view of the end to be sought ; in particular, the lamp and the dynamo must be considered as two parts of one whole. 2. The best method to secure a good light service in ordinary conditions consists in uniting in each establishment two similar machines, each capable of furnishing two currents of 25 and 50 amperes. The employment of currents above 100 amperes would not be justified in the French "feu-éclair" apparatus. 3. The De Méritens magneto machine is particularly appropriate for this service, and the only serious objection to be raised against it is its comparatively high price. 4. The construction of a continous or alternate current machine, capable of replacing the magnetos, while preserving the same advantages, is not so easy a task as electricians are tempted to think it. The best proof of this is in the absolute or partial failure that has attended the efforts of manufacturers of repute in other countries as well as in France. 5. The attempts made have, nevertheless, shown the possibility of obtaining alternators suited to the service at a very moderate price, and of better efficiency than that of the magnetos, and perhaps at a later period continuous-current dynamos, having similar properties, by using a special method of compounding. The alternators will give us the safety and regularity that (continuous-current) dynamos will obtain with difficulty. 6. The comparative results obtained in the optical apparatus now in use show a considerable superiority in the alternate currents in respect of luminous efficiency. But these apparatus not being the best suited to continuous currents, it may be objected that an apparatus specially constructed for them might utilise the energy expended nearly to the same extent realised with alternate currents. However that may be, the latter exhibit at present advantages of all kinds which are of a nature to justify the preference that has been given them for lighthouse lighting.

* We have not quoted in this table the figures of 1,800,000 becs, or 332 per watt, mentioned above, for the current of 98 amperes at 57 volts, because the 500,000 becs of increase were only gained by the excessive diminution of the negative carbon (18mm. instead of 23), with which such a condition could not be maintained. It produces, also, too great irregularity ; the power varying from 580,000 to 3,200,000 becs, while in the normal *régime* the power only varied from 1,300,000 to 3,130,000 becs.

* MM. Sautter, Harlé and Co. have recently proposed a still more radical project, consisting in a Mangin projector revolving over a bath of mercury like the "feu-éclair."

† Abstract from the *Elektrotechnisches Echo*, July 15 and 22, 1893.

THE BOCKENHEIM ELECTRICITY WORKS.†

The Bockenheim Works, though of no great extent, are somewhat remarkable, as being the only station where alternate are transformed into direct currents before use. Bockenheim, although rejoicing in a separate municipal authority, is in reality only a kind of industrial suburb of Frankfort, and the chief consumers, therefore, are factories, a large number of which are of small size ; there is practically no private lighting. Local considerations pointed to a high-pressure system as necessary, and to a distribution so arranged as to be suitable for motors ; and the Lahmeyer alternate direct current-system shown at the Frankfort Exhibition was chosen as most suitable for the purpose, and the work was therefore entrusted to Messrs. W. Lahmeyer and Co., of Frankfort, who began in the summer of 1892, and started running in December. The engines are tandem compound condensing machines of 200 H.P., which can be raised to 260 H.P. in an emergency, and run at 96 revolutions per minute. The low-pressure alternators are coupled directly to the engines, and have rotating field-magnets inside a stationary armature, and are 80-volt three-phase machines. Two 30-kilowatt direct-current machines are driven by belts from the fly-wheels of the engines, and serve not only for producing the energy required for lighting and for small motors, but also for exciting the alternators and for charging accumulators in the day-time.

The alternate currents are transformed up to 660 volts at the station, and distributed by means of a cable network to motors, and to three-phase dynamotors, producing direct currents, which feed into the direct-current cable system, and are aided by the above-mentioned direct-current dynamos. The object of this arrangement is, by the multiplication of transformers, and therefore of feeding points, to reduce the drop in the mains, and thus

Digitized by Google

save copper. The current is supplied to four distributing centres direct from the station, and the remainder are fed from the transformer sub-station. The transformer is simply a three-phase motor with an extra winding, commutator, &c., giving direct currents. The three-phase network is calculated to supply an aggregate of about 300 H.P. for motors, and the direct current system to take 4,000 lamps (8 c p.).

It is interesting to note that before the station was made the total expenditure of energy in motive power in Bockenheim was about 400 H.P., and of this, after less than a year, 160 H.P. are on the electric mains, and applications have been received for 50 H.P. more.

TRADE NOTES AND NOTICES.

[Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.]

The 1893 Edition of "THE ELECTRICIAN" Electrical Trades' Directory and Handbook is NOW READY. This useful book contains over 1,000 pages, and several new and handy features have been added. Price 7s. 6d., post free 8s. 3d.; abroad 8s. 10d. *Comparison with any similar electrical publication is specially invited.*

TENDERS INVITED.—The Guardians of the Woodstock Union invite tenders for supplying and fixing electric bells in the workhouse. Tenders must be in by to-morrow (Saturday).

TENDER ACCEPTED.—The St. Pancras Vestry have accepted the tender of Messrs. Johnson and Phillips for their "D. P." accumulators for the extension of the Regent's Park central station.

SALES BY AUCTION.—Messrs. Wheatley Kirk, Price and Goulty announce in our advertisement columns that their sale by auction of the contents of the works and show-rooms of Messrs. Fawkner, Rogers and Co., at 11 and 12, New Bridge-street, London, E.C., will take place on Thursday next, the 7th inst. The sale will include steam and gas engines, three new dynamos, lathes, planing, drilling, and screwing machines, shafting, fans, &c.; and the lots may be viewed on Wednesday and on the morning of the sale. Catalogues may be obtained from the auctioneers, 49, Queen Victoria-street, E.C.; from the receiver, Mr. H. Jackson, 53, Coleman-street, E.C.; and from Mr. T. G. Vickery, Church Court-chambers, Old Jewry, E.C.

——— Messrs. Wheatley Kirk, Price and Goulty also announce that the sale of the plant, &c., of the Northern Telegraph Works, Halifax, will take place on September 12th, 13th, 14th, and 15th, instead of as previously announced. The advertisement in another column gives some particulars of the plant, machinery, fittings, patterns and drawings, patent rights, &c., to be included in the sale; and catalogues are to be obtained from the Auctioneers, 49, Queen Victoria-street, London, E.C., and Albert-square, Manchester; and from Messrs. Lakeman and Olliver, 44, Prudential-buildings, Park-row, Leeds.

TELEPHONE INSTRUMENTS AND STORES FOR SALE.—The National Telephone Company invite tenders for a large quantity of old instruments and stores, particulars of which can be obtained of the Stores Department, Oxford-court, Cannon-street, E.C.

EXHIBITION.—A Universal Exhibition is to be held in Madrid from April to October, 1894. A circular has been issued inviting English manufacturers to participate.

PRESENTATION.—Mr. Vincent Swindells, who was connected with the Mutual Telephone Company from its foundation, and later with the New Telephone Company at Manchester, has been presented by his colleagues with a handsome testimonial, upon his leaving to assume the representation in the North of England of the Fowler-Waring Cables Company (Limited).

FAILURE.—Before the Leeds Official Receiver in Bankruptcy, on Thursday last week, a meeting was held of the creditors of Harry Austin and James Myers, trading as Austin and Myers, manufacturing electricians and electrical engineers, Armley. The joint liabilities were stated to be £261. 18s. 11d., and assets £79. 4s. 6d. The debtors attributed their difficulties to cost of advertising and bad debts. No resolution was passed.

LIQUIDATIONS.—The Société Française d'Accumulateurs électriques Faure-Sellon-Volckmar is to be voluntarily wound up.

LIQUIDATIONS.—The first meeting of creditors of the International Electric Syndicate (Limited), which was ordered to be wound up in November last, will be held at 33, Carey-street, Lincoln's Inn, W.C., on September 7th, at 11 a.m.

——— Mr. Stuart Lowden, accountant, of Pontefract, has been appointed liquidator of Mountain's Wire Manufacturing Company (Limited) (in liquidation).

MESSRS. RUSSELL AND CO.—This firm inform us that they have taken over the contracting business hitherto carried on by Mr. Medhurst at Cambridge, and have work in progress at several of the colleges. Their local office is 6, St. Andrew's-street, Cambridge.

MESSRS. J. H. HOLMES AND CO.—This firm have obtained the contract to light by electricity the newly-erected premises of the Prudential Assurance Society at Newcastle-on-Tyne.

ELECTRIC PUMPING PLANT.—We learn that the Corlett Electrical Engineering Company (Limited) have secured a contract for supplying and erecting a large pumping plant for the Consett Iron Company (Limited). It will consist of a three-throw ram pump driven by an electric motor, and two centrifugal pumps, each coupled direct to an electric motor. The current for all three motors will be supplied from a dynamo to be placed in an engine-house on the surface and situated about a mile and a-half from the pumps.

MINING MACHINERY.—The Jeffrey Manufacturing Company are introducing their machines to the colliery proprietors of Great Britain. Their machines include one for undercutting coal, which the Company claims takes a cut of 3ft. wide and up to 6ft. deep in about 20 minutes; and a drill which is stated to bore a hole for blasting 2in. diameter by 6ft. deep in about two minutes. The English business will be worked by Messrs. John Davis and Son, who have undertaken the management for the United Kingdom. Electric motive power is usually employed, and the machines for safety lamp pits will be fitted with the Davis and Stokes safety motor.

THE LEEDS AND LONDON ELECTRIC ENGINEERING COMPANY.—This Company, with which Mr. Robert Hammond is intimately associated, have sent us a well-illustrated catalogue of Lowrie-Hall transformers, fuses, switches, and fault-detectors, and surface and junction boxes, as used by the various supply companies with which Mr. Hammond is connected. The appliances, all of which are under Lowrie-Hall patents, are of substantial design, and apparently well suited for their work.

MESSRS. R. CRITTALL AND CO.'S CATALOGUE.—Messrs. Crittall and Co. have sent us a catalogue of door furniture, electric light switch covers, and panels for switches and cut-outs. The work is for the most part low relief chased *repoussée*, and is produced by electrotyping from original models. The artistic design excels anything that we have seen for a long time, and is altogether on a different level from the gaudy and ostentatious styles to which we have so often objected. Switches are as a rule only one degree less hideous excrescences in a well-decorated room than cut-outs. The latter are fortunately relegated for the most part to distributing boards, but Messrs. Crittall and Co. illustrate some beautiful panels with sets of switches and cut-outs. Electric bell pushes are treated in the same style.

MESSRS. COLE, MARCHANT AND MORLEY.—This firm have sent us a catalogue of steam engines, and call attention to their automatic positive Corliss engine, with Morley's patent gear, which they recommend for electrical work.

ELEKTRICITÄTS-GESELLSCHAFT HAMBURG.—We have received from this Company a price-list of their "Venus" and "Bifilar" incandescent lamps, together with an intimation that the increasing sale of these lamps has rendered necessary an enlargement of their works.

ELECTRICITY *v.* GAS.—The annual report of the North-Eastern Sanitary Inspection Association, just issued, states, with regard to the electric light, that "not only is it purer, and consequently healthier, than gas, but that, light for light, it is only a little dearer than the older illuminant."

BARTON.—The Workhouse Extension Committee are preparing a report for the Board of Guardians on the subject of the relative cost of the electric light and gas.

BRISTOL.—The local Gas Company held its half-yearly meeting last week, and Mr. Alderman J. W. S. Dix, who presided, said he thought the power which Corporations had of carrying on electric lighting works at the cost of the ratepayers was unfair to the gas companies, who were in most cases probably the largest ratepayers.

Digitized by Google

He looked forward without concern to the competition which the Bristol Gas Company would shortly have with the electric light. The maximum dividend was declared.——The Industrial and Fine Arts Exhibition, opened on Monday, is lighted by electricity generated at the Corporation's new central station. In the building are 20 arc lamps of 1,000 c.p. each, and between 300 and 400 incandescent lamps, mainly of 16 c.p. The industrial section is illuminated by 18 arc lamps, arranged in two series on circuits of 105 volts, and underneath the galleries, and elsewhere where necessary, are incandescent lamps. The arts section is lighted entirely with incandescent lamps, electroliers of numerous designs being brought into requisition. The electric current from the Corporation works is conveyed to a station within the building, which is an exact model of the numerous sub-stations in different parts of the city which the Corporation will own. From this chamber the whole of the lamps in the Exhibition will be controlled. The search-light in one of the towers is to be ready shortly. All the arrangements for the illumination have been carried out by the Electric Lighting Committee of the Exhibition, under the direction of Mr. H. Faraday Proctor, the resident electrical engineer to the Bristol Corporation, who is a member of that Committee.

CANTERBURY.—The Brush Company have intimated their acceptance of the agreement for the transfer of the Electric Lighting Provisional Order for Canterbury, and the installation will now be proceeded with.

EDINBURGH.—The Lord Provost will turn on the electric light at the Powderhall Refuse Works between 7 and 9 o'clock on the evening of September 11th.

FALMOUTH.—An exhibition is to be held in the Polytechnic Hall, which is to be lighted by electricity for the occasion. Messrs. Veale have received instructions from Mr. J. Grose (ex-Mayor) to instal the electric light in his new premises, which include several large shops.

FORT WILLIAM (CALCUTTA).—The proposal to light Fort William by electricity, which has been under consideration for some years, has been negatived owing to want of funds.

KIDDERMINSTER.—A few weeks ago circulars were sent out to the inhabitants by the Improvement Committee of the Town Council with the idea of ascertaining the probable demand for the electric light if the Corporation should decide to take up the matter, and at a recent meeting of the Council the Mayor said that the majority of the replies had been received, and a report was being prepared.

RICHMOND.—The construction of the electric light buildings at Richmond has been temporarily delayed by the going out on strike of 50 men, who have, however, now returned to work.

TAUNTON.—The electric Lighting Committee of the Town Council recommend that the purchase of the electric lighting works should be completed by September 30th, that Dr. J. A. Fleming, F.R.S., be appointed consulting engineer for one year, and that the services of Mr. H. E. Hunt as electrical engineer be retained at a salary of £150 per annum. The recommendations have been adopted.

TOTNES.—An attempt to introduce electric bells for summoning the members of the Fire Brigade on an outbreak of fire has lamentably failed, to the great satisfaction of some members of the Town Council, who consider that as "the church bells have sufficed for hundreds of years the practice of ringing them in case of fire should be continued." The introduction of the electric bells would have entailed a capital outlay of £13. 7s. 6d., and an annual charge of £1 for repairs.

WINDSOR.—Messrs. Roger Dawson (Limited) have agreed to rent the works and plant of the Windsor and Eton Electric Lighting Company (Limited) for the purpose of supplying the existing customers and to prevent the deterioration of the plant; and the current is now being supplied by the first-named Company. Efforts are being made to induce the Corporation to take into their own hands the question of the electric light.

BOOKS RECEIVED.

"Griffin's Electrical Price Book." By H. J. Dowsing. (London: Charles Griffin and Co.)

"Institute of Chemistry of Great Britain and Ireland." Regulations for admission to membership and register. Issued by Council, April, 1893.

"Journal of the Institution of Electrical Engineers." (London: E. and F. N. Spon.)

PATENT RECORD.

A record of Applications for Patents and Patent Specifications Published is compiled for this journal by MR. J. C. CHAPMAN, *Fel. Chartered Inst. Patent Agents, of 70, Chancery-lane, W.C., from whom any information on the subject may be obtained.*

APPLICATIONS FOR PATENTS.

NOTE.—*The Specifications of Applications for Patents are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions, or where complete specification accompanies application an asterisk is suffixed.*

August 5, 1893.

15,050. H. OPPENHEIMER. London. Slow striking electric bells.

15,064. F. W. and S. J. SUTER. London. An improved electric arc lamp.

15,073. H. H. COOPER and THE ELECTRICAL INSTALLATION COMPANY (LIMITED). London. Improvements in electric arc lamps.

15,074. H. H. COOPER and the ELECTRICAL INSTALLATION COMPANY (LIMITED). London. An improved electric coupling.

August 8, 1893.

15,110. F. A. PERRET. Manchester. Improvements in apparatus and devices for starting, stopping, and reversing electromotors.*

15,151. F. S. PALMER. London. Improvements in circuit-testing apparatus.*

15,156. P. RABBIDGE. London. Improvements relating to telephones.

August 9, 1893.

15,198. L. B. MILLER and M. W. WOODS. London. Improvements in apparatus for obtaining ignition by means of electricity.

15,217. G. C. DYMOND. Liverpool. Improvements in electric cables.

6,907. Best. Chandeliers and electroliers.
9,039. Denison. Autographic telegraph apparatus.
9,819. Hall. Electric circuit controlling devices.
11,464. Thompson (Biermanns). Galvano electric belt.
11,819. Allen. Electric railway trollys.
12,374. Gover. Electric lamps.

NEW COMPANIES, STATUTORY RETURNS, &c.

[*In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in* "The Electrician" Electrical Trades' Directory and Handbook, 1893, pages 320-348, *&c., &c.*]

AMERICAN INSULATED WIRE COMPANY (LIMITED).—In consequence of the non-completion of the arrangements for the purchase of an insulated wire manufacturing business in America this Company desires erasure from the register, as no business of any kind has been done.

T. S. McINNES AND CO. (LIMITED).—This Company was registered last week, with a capital of £3,000, in 1,000 Preference and 2,000 Ordinary shares of £1 each. The objects are to carry on the business of electrical and scientific instrument makers, &c., in continuation or extension of the business at present carried on by the firm of T. S. McInnes and Co., Glasgow.

ARC ACCUMULATOR COMPANY (LIMITED).—The recently-filed returns of this Company for 1892 and 1893 show that only the seven signatories' shares have been allotted, no payments having been requested.

ATLAS CARBON MANUFACTURING COMPANY (LIMITED).—The annual return of this Company, made up to June 11th, has been filed, and shows that the whole nominal capital of £2,000, in shares of £1 each, have been allotted as fully paid.

BOARDMAN'S ELECTRIC SUN LAMP PATENTS (LIMITED).—The statutory return of this Company, made up to July 18, 1892, was recently filed, when seven shares out of a capital of £10,000, in £5 shares, were taken up, and the full amounts called and paid on them.

BRITISH ELECTRIC TRAMWAYS AND GENERAL SYNDICATE (LIMITED). The annual return of this Company, made up to July 28th, has been filed. The Company has a nominal capital of £10,000, divided into 1,850 "A" and 150 Founders' shares of £5 each. 7 "A" and 87 Founders' have been taken up. No calls have been made on the former, while the full amount has been called and £435 paid on the latter class of shares.

CITY NOTES, &c.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended August 27th were £716, as against £805 for the corresponding period of last year, being a decrease of £89. The total receipts for the half-year amount to £6,628, against £6,190 in the corresponding period of 1892, being an increase of £438.

DIRECT CABLE COMMUNICATION WITH SPAIN.—The Direct Spanish Telegraph Company's Falmouth-Bilbao cable has been repaired, and direct cable communication by Spain with that route is now restored.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announces the connection, by submarine telegraph cable, of the Islands of the Azores with Lisbon and the general system of cables. Telegrams are accepted for delivery in the Islands at the tariff of 10d. per word, and should be handed in at postal telegraph stations marked "*Vid* Eastern."

STOCK EXCHANGE NOTICES.—Applications have been made to the Stock Exchange Committee to allow the following securities to be quoted in the Official List: Brush Electrical Engineering Company, further issue of 15,000 Preference shares and 10,000 Ordinary shares; Commercial Cable Company, further issue of $2,284,000 capital stock; Electric Construction Company, Ordinary shares in lieu of those of the old Corporation.——The Committee appointed Tuesday last, the 29th ult., a special settling day in the £200,000 (part of £300,000) Four per Cent. Registered Mortgage Debentures, Nos. 1 to 8,000, of the Eastern and South African Telegraph Company (Limited) (Mauritius Subsidy); and they have ordered these securities, and the further issue of 25,730 Ordinary

Digitized by Google

shares Nos. 458,868 to 484,597 28,284 Five per Cent. Non-Cumulative Third Preference shares, Nos. 90,951 to 119,234, and £198,540 (part of £273,523) Four and a-Half per Cent. Debenture stock of the National Telephone Company (Limited), to be quoted in the Official List.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended August 25, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £2,810.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 799.—Vol. XXXI. FRIDAY, SEPTEMBER 8, 1893. PRICE FOURPENCE.
Annual Subscription (U.K.), 19/6

NOTES.

Among the electrical Papers which have been promised for Section A of the British Association are two by Lord Kelvin, "On the Piezo Electric Property of Quartz" and "On a Piezo Electric Pile." Mr. E. H. Barton will read a Paper on "Electrical Interference Phenomena, somewhat analogous to Newton's Rings, but exhibited by Waves in Wires," and the other Papers will be "The Passage of Electric Waves through Layers of Electrolyte," by G. H. Yule; "On Standards of Low Electrical Resistance," by Prof. J. Viriamu Jones; "The Specific Resistance of Sea Water," by W. H. Preece; and "An Alternating-Current Potentiometer," by James Swinburne. Among the reports will be "Electrical Standards" and "Magnetic Work at Falmouth Observatory."

The principle of sacrificing efficiency in order to prolong life or reduce depreciation is one which is applied in more than one industrial process or invention. The Paper read by Mr. L. B. Marks at the International Electrical Congress, at Chicago, which will be found in another column, is a further illustration of this principle, as applied to electric lighting. By enclosing the electric arc in a confined space, thereby depriving it of free oxygen, and allowing the development of a pressure considerably greater than that of the atmosphere, Mr. Marks has succeeded in maintaining the arc with a very reduced consumption of carbon, but requiring an amount of power per candle considerably above the normal. The precise point at which such a practice ceases to be economical will, of course, depend upon the relative cost of energy and of carbon, as well as on the cost of labour in trimming; and it must not be forgotten, in estimating the commercial value of the incandescent arc invented by Mr. Marks, that in this country the consumption of arc-lamp carbon for a given amount of light has been reduced, by other and more simple means, to a value far below that which is now common in America.

The phenomenon of a cylinder full of soft refulgent light, which it is claimed that this lamp produces instead of the sharp local arc, is one which, if it could be obtained with unimpaired efficiency would, serve a better purpose than the usual arc. But it must not be forgotten that such a phenomenon, where large candle-power is concerned, is impossible in a purely gaseous and transparent atmosphere; and that, on the contrary, the very existence of this translucence of the enclosed atmosphere implies the existence of smoky vapour or finely-divided particles of carbon in the enclosed space around the arc. This, together with the inevitable incrustation of solid carbon on the surrounding glass cylinder, must greatly tend to reduce the efficiency, and to increase the cost of cleaning, the lamp.

A striking series of experiments on contrast colours is described in the August number of the *Phil. Mag.* by Prof. Alfred M. Mayer; and considerable interest attaches to them owing to the bearing they have on photometry. The difficulty arising in judging the relative candle-power of two lights which differ in colour is well known. It is often got over by the use of red and green glasses. But the objection to this method is that it gives two results, neither of which is the one wanted, and which cannot be combined together to yield the value required. The true illuminating power can only be estimated by judging the intensity of the two parts of the photometer disc in spite of colour differences; and after a little practice this can be done with a degree of accuracy quite sufficient for most purposes. The colour difference between the lights which are being compared always appears greater than it really is, owing to a peculiar optical effect, the reason for which is not yet satisfactorily settled. It is well known that dark spots on a coloured background appear coloured, the hue being complementary to that of the background. Thus black spots on a red ground appear green, while if the ground is green, they seem red. This effect has to be taken into consideration by artists, and it occurs with a Bunsen, or other similar, photometer when the lights compared are of different colours, the two parts of the screen appearing, by contrast, in complimentary hues.

It is this contrast effect that Prof. Alfred Mayer has set himself to investigate, and the experiments he describes are both simple and convincing. Among other results he proves that the perception of these effects is instantaneous. The ignorance hitherto enveloping this subject is shown by the fact that the contrast colour observed has always been attributed to an "error of judgment" on the part of the eye. As, however, the effect takes place when the colours are only seen by the instantaneous flash of an electric spark, it is no longer possible to hold this theory, unless it is assumed that the mental operations necessary for this judgment can occur in less than one-millionth of a

Digitized by Google

second. Probably what is necessary to see these effects is not so much a minimum interval of time as a minimum amount of light. The electric spark, although only "momentary," gives out an appreciable quantity of light. Incidentally also these experiments give evidence in favour of HERING's theory of colour, as opposed to the usually accepted theory of YOUNG and HELMHOLTZ, and it is therefore specially appropriate that, in a later part of the same number of the *Phil. Mag.*, Dr. WILLIAM POLE gives an abstract of Prof. HERING's little known theory of colour, in connection with the explanation of colour blindness. Prof. ALFRED MAYER's Paper concludes with the description of a new photometer, specially designed for the measurement of coloured lights. This is an ingenious instrument, by means of which the quality of the colour of any light tested can be accurately measured. It is not suitable for commercial work, although of great scientific interest.

THE determination of the solubility of salts so sparingly soluble that they are generally ranked as typically insoluble substances, is no easy matter. The evaporation of a known quantity of a saturated solvent and the weighing of the residue constitute a tedious and inexact process when a litre or more of liquid has to be got rid of, and a milligram or less of the dissolved solid remains to be weighed. An attempt has recently been made by HOLLEMAN to compute the solubility of such substances—of which barium sulphate will serve as an example—from the determination of the electrical conductivity of their solutions. According to modern views, solutions when of great tenuity contain the ions of the dissolved salts in a state of dissociation, and even saturated solutions of bodies which are, in ordinary parlance, insoluble, are sufficiently dilute to fulfil this condition. The electrical conductivity of a solution of a dissociated salt is proportional to the number of ions, and hence to the quantity of the salt, present. These principles can obviously be applied to the determination of the solubility of every salt in dilute solution.

SOME of the values obtained in this manner are of considerable interest. Thus barium sulphate is soluble in 429,700 parts of water at 18·9°C., and in 320,000 parts at 37·7°C., the effect of temperature being therefore considerable. On the other hand, the analogous salt strontium sulphate is soluble in rather more than 10,000 parts of water alike at 16°C. and 26°C. The amount of water required for the solution of silver chloride at 13·8°C. is 715,800 parts, and falls to nearly half its value at 26·5°C., being then only 384,100. As might have been supposed, the most nearly insoluble salt hitherto examined is silver bromide, which needs no less than 1,971,650 parts of water for its solution at 20·2°C., while the next is silver bromide requiring 1,074,040 parts at 28·4°C. It would be instructive to compare the figures for these three halogen salts of silver at the same temperature and ascertain what relation exists between them. Such a comparison is possible with the carbonates of barium, strontium, and calcium, as their solubilities have been determined at 8·8°C., giving the values 64,070, 121,760, and 99,500. Unfortunately, however, if this group of metals be regarded, strontium must be looked upon as the middle member, so that the fact that an extreme value has been obtained for the solubility of its carbonate makes confirmation of the precision of the determination requisite before an explanation can be profitably sought.

THE fussy and wearisome cross-questioning to which the POSTMASTER-GENERAL continues to be subjected in regard to the agreement with the National Telephone Company no doubt serves to bring the questioners into undue Parliamentary prominence, but the opportunity of rendering any real public service occurred more than three years ago, and was allowed to slip. By the terms of the telephone licences the POSTMASTER-GENERAL is empowered to exercise his option of purchase at certain stated intervals. It was in June, 1890, that the first opportunity arose, and it is not until June, 1897, that the next will occur. No doubt Government purchase could take place in the intervening period, though upon comparatively onerous conditions. Such being the case it would surely have been better for Parliament and the Post Office to have employed the seven years of reflection they had given themselves in definitely deciding what they meant to do in this matter of telephonic communication, rather than in snarling and nibbling. In April, 1892—that is to say, exactly two years too late—Dr. CAMERON moved the purchase of the telephones, and was defeated by a large majority. A few weeks later we were, nevertheless, treated to a Treasury minute and a Telegraph Act, which committed the country to the half-hearted policy of trunk-wire purchase. And now, having by indecision placed the public interest at a disadvantage, our legislators are trying in futile fashion to get out of the muddle by badgering the POSTMASTER-GENERAL. The Post Office may be trusted to make as good a bargain as the circumstances of the case permit, and if the public is not altogether satisfied with the result it will at least know who is to blame.

"ALTHOUGH we may never know what electricity really is," says a New York contemporary, "any more than we now know what is life or the force of gravity, might we not at the present Electrical Congress plant a milestone in the progress of science by stating what we, at the present time think it is?" Our contemporary ventures to suggest that an electric circuit may be "an exaggerated atom," since both an atom and an electric current have been explained on a vortex hypothesis. This is something to go on with—a kind of hole into which the milestone may be planted. The difficulty which is likely to arise, however, is that other people of as undoubted authority as the Chicago Congress will also "plant milestones" recording their thoughts about the nature of electricity, so that when MACAULAY's New Zealander reviews the past, he is likely to be confused by the conflicting records. The present state of our knowledge about the nature of electricity is too speculative, too imperfect, to justify anything of the nature of a manifesto, ukase, or "milestone" wherewith to pass it on to posterity.

THE American electrical journals which come to hand just as we go to press contain the report of the delegates of the

Digitized by Google

International Electrical Congress at Chicago. The ohm, the ampere, the volt, the coulomb, the farad, the joule, the watt, and the henry have been adopted; and the Congress recommends the several Governments represented to formally adopt them as legal units of electrical measure. A committee appointed to consider the standard of light was unable to recommend the adoption either of the Von Hefner lamp or the pentane lamp. M. HOSPITALIER'S system of notation and symbols was not officially adopted.

Telephonic Communication between Norway and Sweden.—Telephonic communication between Stockholm and Christiania was opened on Saturday last week.

Cable Interruptions.—

	Dates of Interruptions.
Paramaribo—Ceara	August 9th.
Aden—Zanzibar	September 1st.

Salford.—The Local Government Board Inquiry, with reference to the proposal of the Salford Corporation to borrow £50,000 for electric lighting, will take place on the 19th inst.

Copper.—Statistics for the end of August show a decline of 1,100 tons on the stock as at the middle of the month, and a net advance of 10s. per ton. The deliveries considerably exceeded those of July.

Obituary.—The death is announced of Mr. Herbert Clifford Saunders, Q.C., at the age of 59. He took much interest in technical education, and had been Chairman of the Executive Committee of the City and Guilds of London Institute for several years.

Torquay.—The Town Council having considered a scheme of electric lighting submitted by a special committee, have decided to defer the matter for six months in view of the proposed consolidation of loans. The scheme was estimated to cost £18,000.

Electric Welding.—The Thomson-Houston Electric Welding Company, of Lynn (Mass.), has discharged all but eight of its *employés*, and the Company will not start again until general business conditions improve. The Company at one time employed 100 hands.

A Large Electric Candelabrum.—The new Parliament buildings in Berlin are to have, in the lobby, a candelabrum 26ft. 8in. in diameter, and carrying 12 arc lamps and 250 incandescents. It is to be decorated with statues of the legendary and historical characters of the Fatherland.

The Niagara Falls Scheme.—The *Electrical Engineer* of New York states that it is informed that on the recommendation of Prof. George Forbes the Cataract Construction Company have adopted Mr. Tesla's multiphase system as the sole method of distribution at Niagara Falls.

Whitehaven.—The municipal central station at Whitehaven was formally opened on Saturday last. The system of supply is the three-wire for domestic lighting and two-wire at 230 volts for public lamps, the lamps being run two in series. The plant capacity of the station is 165 kilowatts.

Railway Station Lighting.—The Great Northern Railway are going to electrically light Finsbury Park and King's Cross Stations. The electricity will be generated at the large works the Company have built at Finsbury Park.

The Sims-Edison Electrical Torpedo.—Preparations are nearly completed for important experiments by the United States Navy, at Newport, for launching the Sims-Edison electrical torpedo from a steamer at sea with a view to introducing it as a naval weapon. This torpedo was adopted three years ago by the United States engineers for coast defence.

Weston Instruments at the Chicago Exhibition.—Weston instruments have been adopted at the suggestion of Prof. Ayrton for all tests made by the Committee of Judges in the Department of Electricity. A laboratory with all the necessary apparatus has been fitted up in the north-west corner of the building, and an exhaustive series of tests will be made.

The Electric Light on May Island.—Last week the Lord Provost of Edinburgh and other members of the Board of Northern Lighthouses accompanied two German officers to May Island for an inspection of the electric appliances in the lighthouse. The visit was in connection with the proposal of the German Government to establish the electric light on Ruegen Island in the Baltic.

The Leeds Tramways.—Sir Douglas Galton, the arbitrator in the dispute between the Leeds Corporation and the Tramways Company, has sent his award regarding the purchase of the latter's undertaking. The effect of the award is practically to reduce the demand of the Company from £250,000 to £112,000 should the basis of valuation contended for by the Corporation be upheld by the High Court.

The Heilmann Electric Locomotive.—In a letter to the *Engineer* Mr. B. H. Thwaite states that he has received information that the Heilmann locomotive ran some trial trips last week. The smooth running was phenomenal; it "quite took the breath out of the railway engineers on the footboard; they could scarcely believe their eyes, their other senses failing to impress them that the engine was actually running."

The Repair of the Falmouth-Bilbao Cable.—The Directors of the Direct Spanish Telegraph Company, in appreciation of the promptitude with which the recent repairs to the Falmouth-Bilbao cable were effected, on Monday last presented Capt. Scott-Smith (captain of the c.s. "Electra") and Mr. Walter Murphy (chief electrician) each with a gold watch, suitably inscribed. The presentation was made by Mr. Ch. Gerhardi, manager of the Direct Spanish Company.

Manchester.—The annual abstract of the accounts of the several departments of the Manchester Corporation for the year ended March 31st last was issued last week. A new account appears this year in connection with the establishment of the electric light. Under the Order which the Corporation obtained in 1890, they were authorised to borrow £80,000 for electric lighting. Up to March 31st they had raised £50,200 of this sum. The total amount expended to March 31st was £41,720, the items being:—Land, £2,161; buildings, £9,337; machinery, £13,196; mains, £14,077; expenses prior to generating electricity, £2,906.

Portsmouth.—At the last meeting of the Town Council the following satisfactory resolution was carried after a brief discussion:—"That the account of the receipts and expenditure of the Electric Lighting Committee, both in respect of capital and income, be kept entirely distinct from all other accounts of the Corporation, so that the financial result of the working of the electric light scheme may be clearly seen; and that a statement showing such result be prepared every six months by the borough accountant, and submitted to the Council through the Finance Committee."

The Trolley Current and Telephone Cables.—Under this heading, Mr. J. Stanford Brown writes to the *Electrical Engineer* of New York, of August 23rd, as follows:—"A new form of trouble due to the grounded return current of the electric railway system in Brooklyn has developed within the last few days. Yesterday, a corps from the telephone company was engaged in removing a large cable from the conduit on Court-street, the lead covering of which had been eaten through by the current from the railway circuit. The foreman stated that this was the first cable from which they had had trouble from this cause. It is very much feared that all the other cables of that line will shortly have to be removed on account of this trouble."

Glasgow.—It is proposed to increase the salary of the Municipal Electrical Engineer to £350 per annum. The Secretary of State for Scotland has authorised the Corporation to borrow another £100,000 in connection with the electric lighting scheme, and on the strength of this sanction the proposed increase in plant has been commenced, the order for the steam engines having been left with Messrs. Siemens Brothers and Co. It is not expected that more than £6,000 will be spent on the proposed extensions. One hundred additional Ferranti meters have also been ordered, experience in Glasgow being very much in their favour.

Digitized by Google

Engineering Courses.—Courses of lectures and laboratory instruction in electricity and other sciences applicable to the industrial arts will be given during the forthcoming winter session at the Royal College of Science, Dublin. Particulars will be found in our advertising columns, and it will be seen that this college offers considerable advantages in the shape of scholarships. Particulars also reach us of the courses of engineering instruction at University College, Liverpool, where a complete system of lectures and laboratory practice under Profs. Oliver Lodge and Hele-Shaw are provided for students in electrical engineering. The session at each of these colleges commences on October 2nd.

Quartz Fibres.—In a Paper recently read before the Franklin Institute, Mr. Northup (of Queen and Co, Philadelphia) states that quartz fibres can be obtained in a similar manner to glass fibres. Any wheel more than 3ft. in diameter and 4in. wide at the rim may be used. The circumference is covered with smooth black paper, across which a strip of fly-paper 1in. wide, with the sticky side up, is pasted. A quartz rod, $\frac{3}{16}$in. to $\frac{1}{4}$in. in diameter, is next prepared and fastened on to a brass rod. The quartz is then melted in the oxy-hydrogen flame, and another rod is then brought in contact with the fused end. By means of this second rod a thread is drawn over the wheel, which is rapidly revolved, and any length of fibre can then be drawn out.

The Municipal Corporations Association and the Telephone Question.—Arrangements have been made for an interview between a deputation from the Municipal Corporations Association and the Postmaster-General to take place after the recess. This interview is the outcome of the following resolution, passed some time since:—"That in the opinion of this Council no statutory powers should be conferred on telephonic undertakers unless statutory obligations and limitations are imposed on the undertakers, and that the Special Committee be requested to consider, as soon as possible, what these statutory obligations and limitations should be, and if they think it advisable to have an interview with the Board of Trade on the subject." The Special Committee interviewed Sir Courtenay Boyle last month, and were referred by him to the Post Office.

Registering Apparatus for Lightning Conductors.—Messrs. Siemens and Halske have lately introduced an apparatus designed for the purpose of registering without in any way interfering with the conductor itself the number of times that a lightning conductor is struck. It is of very simple construction; a cast iron box with suitable lugs carries the working parts, consisting of a simple iron bar which is magnetised by the current in the conductor, and deflected against the control of a spring, moving the hand on one division; a screw stop prevents its moving more than the right amount. All the works are fastened to the cover of the box so as to be easily accessible, and the sensibility is so arranged that a momentary current of at least 250 amperes is required to move the pointer.

Electric Car "Fenders."—The frequent accidents arising from the introduction of high-speed electric cars has led the inventive American mind to devise an appropriate form of "car fender." The form of "fender" now in use on the line between Lynn and Boston is a frame of ∿-shaped steel wire, the lower bar being covered with rubber. It may be run close to the track or lifted high above it, the height being controlled by a releasing device operated by the knee of the motor-man. Repeated trials on dummies placed on the track have, it is said, demonstrated that this "fender" will pick up man, woman, or child, and carry them along without harm, no matter in what position they may be when struck, or what the speed of the car may be. We are not informed whether the individuals so transported are taken free of charge.

The Electric Lighting of the Southampton Free Library.—At a meeting last week of the Southampton Free Library Committee, the Librarian stated that for 26 days the consumption of gas was 13,500ft., or an average of about 515ft. per day. The number of lamps of 16 c.p. was 67. The consumption of gas per hour was at first 207ft.; but Messrs. Crossley were not satisfied with that, and they sent down their chief inspector, who succeeded in reducing it to about 200ft., and it was anticipated that this would be succeeded by a further reduction. Whereas for lighting they now incurred an annual expenditure of £96; if they burned gas the cost would be £100; but inasmuch as in ten years' time the plant would be their own property, as it would then have been paid for, the £96 would be reduced by £47. 10s., representing a saving of nearly £50 a year.

A Coal Dust Engine.—A novel motive-power engine, says the *Engineering and Mining Journal* of New York, has been patented by a German engineer, and it is said that Herr Krupp is now constructing an experimental engine to test its practicability. The engine is based upon the fact that very finely divided carbon, floating in the air, readily explodes, and to adapt this to the generation of motive-power the inventor proposes to grind coal to an impalpable powder, and, after introducing the dust floating in the air into the cylinder of an engine, explode it, the idea being to follow very much the same lines which are being so thoroughly developed in the use of gas in engine practice. The first difficulty which suggested itself is how the ash is to be got rid of; but Herr Krupp says that his experience in gun manufacture convinces him that this is not a serious obstacle.

Non-Inductive Resistances.—At a recent meeting of the Société Française de Physique, M. E. Ducretet described a method he had employed for making high resistances without self-induction, and hence suitable for use with a telephone in Kohlrausch's method of measuring resistances. He uses a zigzag formed on platinised glass, very like that composed of fine platinum wire used by M. Mergier, and finds that a piece of platinised glass 75mm. by 110mm., allows of the construction of resistances varying from 25 to 100,000 ohms. The glass plates are fixed in a glass vessel by means of an insulating cover, and this vessel is filled with purified petroleum, which M. Pellat has shown to be a very good insulator. In this manner all effects due to moisture in the air are removed, while it is easy to measure the temperature. A layer of mercury of variable thickness at the bottom of the vessel allows of the resistance being adjusted to any desired value.

Electric Street Car Ambulance.—St. Louis, says the *Street Railway Review*, seems to have a quicker appreciation of the adaptation of the electric railway than any other city. She started with a postal mail car, the first of its kind in the world, and now proposes to put in service an ambulance car. The idea originated with Dr. George Homan, the city health commissioner, and promises to become a most important auxiliary in the work of his department, the object being to displace horse vehicles in conveying patients to the hospitals. The three large hospitals of St. Louis are some miles distant from the central part of the city, where the city dispensary is situated, and from which place all cases are forwarded. All the hospitals are in near relation to, or directly on the route of, one of the principal railway systems of St. Louis, and this fact was one of the considerations that determined the employment of this class of vehicle for the purpose stated. Of course, a special car will be required, and extra springs will be placed under the car body to make the journey as smooth as possible.

A Suggestion.—A correspondent in the Southern Hemisphere—it is not necessary to name the country—sends us the following suggestion. As we do not presume to understand it, we print it exactly as he wrote it. Lord Cross's committee, with the assistance of experts and Government scientific officers, might have made something of it. A committee of Section A of the British Association might be appointed to determine whether the "dry place" or the batteries themselves should be 6ft. high:—

"Observing in a recent issue of *The Electrition* an account of the friction that exists between the Electric traction Coys and the Telephone Coys in England it has occured to me that if the Telephone Coys would use Insulated airial wires on a metalic circuit it would obviate the difficulty. Get one of the Telephone Coys to try the following; run Hoopers tape covered wire (or any other well insulated wire) the whole length of the worst section they have, the wires may be run on the existing poles and brackets but as a precautionary measure when the present wires are disconnected from the Instruments they might be connected to the nearest known good earth, have the batteries standing in a dry place, about six feet high covered in and well insulated from the ground; this ought to prevent all induction from the other Coys wires, and it ought to reduce the danger

Digitized by Google

when using the Telephone during a thunderstorm to a minimum. Have the Instruments fitted up in a room where deafening has been used all round, they might also erect a protecting board over the Instruments at such a heighth that the persons using them could stand upright and move with freedom, this will protect the Microphone from all exterior noises such as from engines factories etc. I am confident that if the above is carried out they will find that the noises complained of will wholly cease."

The "New Beacon Non-Infringing" Incandescent Lamp.—The rapidity with which perfectly "new," entirely "non-infringing" incandescent lamps are by pressure of circumstances being brought out in the United States is positively alarming. Here we have the Beacon Vacuum Pump and Electrical Company of Boston, not content with having evolved a non-mercurial air pump for exhausting glow-lamp bulbs, and having temporarily upset the Edison monopoly, now offering the public yet another lamp. In this lamp the neck of the bulb is provided with two shoulders, supporting two thin mica discs. The upper disc serves as a support to a cement plug, which is poured in in a fused state, and completely fills the upper part of the neck. This cement, we are told, "is of a novel composition, and is not only absolutely impervious to air itself, but makes an equally air-tight union or joint with the glass surface of the lamp neck. It is able to withstand the temperature to which it is subjected in the operating lamp without leaking or giving off any gases or vapour whatsoever." Notwithstanding this, however, the function of the lower mica disc is to act as a reflector and "throw back the heat of the filament, thereby keeping the cement plug from being affected." Not only so, but in the space between the two mica discs, are four small circular metallic discs strung upon the leading-in wires, which are of iron, and the function of these, we are told, is to "take up the heat of the leading-in wires and disperse it by radiation, preventing it from being carried into the cement plug." With much care bestowed upon the single point of keeping the cement plug cool, the statement that "while the lamp is burning the cap and socket are nearly as cool as when it is not in operation" ought certainly to be correct.

Electric Travelling Crane at Creusôt.—At the works of MM. Schneider et Cie., of Creusôt, a series of electrically-driven cranes have been constructed and put in operation. The first was an adaptation of a 45-ton rope-driven crane, the second was a 60-ton crane, and the third—a detailed account and numerous scale drawings of which are to be found in a recent number of *Engineering*—is a 150-ton crane, specially constructed to work by electricity. This crane is fitted with two 45-kilowatt continuous-current motors of the Ganz type. The current is supplied to these by means of two bare copper cables running the entire length of the parallel supporting girders. These cables rest on the tops of porcelain insulators supported on brackets; and they pass through hollow carbon brushes or collectors, by means of which the current is circuited through the motors. As these hollow brushes pass the porcelain brackets the copper cables are lifted from their position on the brackets. The generator is a 100-kilowatt four-pole Ganz machine, and it supplies the motors at 220 volts. Both the generator and motors are compound-wound. The attendant's cabin, in which the machinery is manipulated, is made of iron plate and angle-irons, and is fixed below the main girders of the traveller; and all the levers and regulating hand-wheels are so grouped that manipulation is easy and as rapid as may be desired. The power is communicated from the motors to the hoisting chain, or to the travelling wheels, as the case may be, by means of helical gear, worm gear, and chains. The chains are composed of built-up steel links with solid steel pins. Three sets of friction clutches enable the hoisting gear to be worked at 3·05ft., 8·23ft., and 11·84ft. per minute respectively, according to the load. These clutches are controlled by forked levers operated by nuts and screws. A band-brake is fitted to the first motion shaft of the crab, and is normally in action. To raise or lower a weight, the gear is first thrown into action, and the brake is then released by means of a foot-lever.

India Rubber Cultivation.—The *India Rubber World* of New York has an article on the lessons that the successful cultivation of the cinchona tree has for those interested in the rubber trade. "By the cultivation of the cinchona tree the world has been assured against exhaustion of the supply of an invaluable remedy, and the price has been reduced until it is no longer profitable to gather free bark and carry it to market. Besides, bark richer in quality has been produced on the plantations. While the cultivation of rubber has attracted little favourable attention so far, no objection has been made to its practicability, that might not have applied with equal force to the cultivation of quinine. The native supply of cinchona trees was so great that exhaustion long seemed impossible; certainly no cultivated product could compete with bark which could be had free, with the cost added of cheap labour for gathering it; perhaps the cultivated bark, in a distant land, would be less rich in alkaloids; besides, a great deal of time would be required for any returns from the investment in planting." Now, it is not known what would be the effect of cultivation upon the india rubber tree with regard to quality, but with regard to quantity Mr. F. O. Harriman's experience in Telmantepec is instructive; on his plantation the cultivated trees are twice as large in diameter as trees of the same age in adjacent forests. "The chief point to consider with regard to rubber culture," concludes the *India Rubber World*, "is not whether we are in danger of exhausting the native supplies—though that has become a practical question in some countries—but whether rubber might not be produced more cheaply under cultivation than it can now be gained in the forests. In addition to the convenience of gathering cultivated rubber, it would be possible to prepare it for market without a great part of the impurities now contained even in the better grades, thus rendering it more desirable for manufacturers. The cultivation of quinine is worth further study for points which may afford suggestions bearing upon the future methods of rubber supply."

A Laboratory Hot-Wire Instrument.—In a recent issue of the *Electrical World* Prof. A. S. Kimball describes a modification of the hot-wire voltmeter used in the laboratory of the Worcester Polytechnic Institute. Four No. 34 German silver wires hang from the ends of adjusting springs placed at the corners of a square hole cut in the top of a tall wooden box. At their lower ends the two wires hanging from the same side of the box are joined by a silk thread, which passes around a thin, loose pulley. The wires on the opposite side of the square are joined similarly by a thread on a second pulley. The wires *diagonally* opposite each other are in metallic connection at their lower ends. From the axis of the two pulleys hangs a plate of metal, with mirror attached. The lower end of the plate hangs in a dish of water to damp its vibrations. If a current be passed through one pair of diagonally opposite metallically-connected wires, the elongation of these wires will allow the suspended systems to rotate one way, and in the opposite direction if the current is sent through the other pair. In fact, the heavy plate has a double bifilar suspension, with oppositely directed couplers, and rotation is caused by varying the length of either pair of suspensions. If both pairs of suspending wires be elongated equally by the same or equal currents, there will be no rotation if the wires are similar and the suspensions are symmetrical. Any desired degree of delicacy may be obtained by regulating the length of the wires, the diameter of the pulleys, &c. Temperature errors are practically eliminated. There are no pivots or delicate moving parts to get out of order. The pulleys do not turn on their axis in use. They only serve to secure equal tension on the wires in the first adjustment of the instrument. The directing force is gravity, and the suspended plate may be made heavy enough to secure perfectly definite indications. Some of the uses to which this instrument may be put are obvious. For example, an alternating current on one pair of suspension wires may be balanced by a direct current in the other wires, and this may be measured by an ammeter. If a suitable switch be used by which the direct and alternating currents may be exchanged on the suspensions, any error of inequality of wires, or want of symmetry in the suspensions may be detected, and the adjustments corrected. In a similar manner, a direct current voltmeter may be used for the measurement of alternating electromotive forces. The sensitiveness may be estimated from the fact that, with the instrument described, which was designed for comparatively large currents, eight volts give a deflection of 256 millimetres on the scale at the distance of one metre.

ELECTRIC MOTIVE POWER.*

BY ALBION T. SNELL.

(*Continued from page 464.*)

It is thus sufficiently clear that a parallel system requires conductors of larger section than those necessary for a series system; and a compromise involving a series transmission and a parallel distribution, is at once suggested.

Let us examine the various methods a little more in detail.

The simple parallel system is shown in Fig. 27. In this the whole of the current necessary for motors *b*, *c*, and *d* has to traverse the two conductors included in the section of the line *a b*, and that required for motors *c* and *d* has to pass through section *b c*, while *c d* only carries the current for motor *d*. Now, the areas of the conductors in the several sections of the line will be suited to the maximum or more probably the average current required to pass through them. There will, therefore, be a different pressure of supply at each of the points *b*, *c*, and *d*. This in itself would not matter if the actual values remained

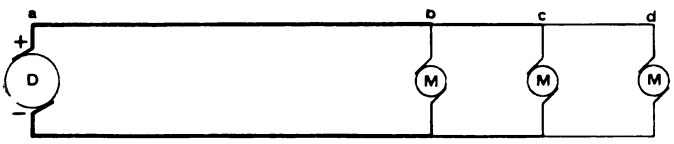

FIG. 27.

constant, but since the pressure of the line varies inversely as the current, it follows that the pressure will be lowest when the three motors are each absorbing their greatest current, and that it will vary at the several points of supply according to the current at each. And the speed of a motor is *proportional to the pressure of supply* for given currents, and therefore the speed will decrease as the load increases from this cause, as well as from the loss over the internal resistance of the motor, which is necessarily greater at large than small loads.

This difficulty is enhanced if the distance from the dynamo to the first motor, from thence to the second motor, and from there to the third motor, &c., be considerable—indeed, in that case, a limit is very soon reached, when the system hopelessly breaks down from the difficulties of regulation already referred to, and from the cost of the enormous weight of copper required to keep the line drop and loss within practicable bounds.

If it be required to cause the pressure at different parts of the circuit to vary approximately equally, the arrangement shown

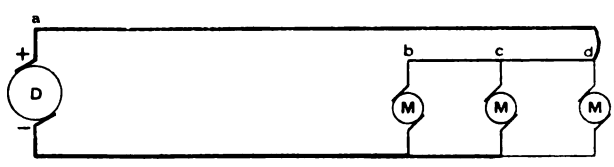

FIG. 28.

in Fig. 28, which is sometimes useful in lighting circuits, may be adopted; but the weight of copper in one of the feeders is evidently increased, and if the distance *a b* be at all considerable compared with *b c* and *c d*, the variation of pressure in the feeders may be so great as to practically outweigh the better regulation gained over the distributors by the looped wire. The scheme at best is but an approximation, and only likely to be used in cases where the motors are not grouped but lie conveniently in a line. In practice, since they are much more likely to lie in a group with some point fairly equidistant from the majority of them, this point will be selected as the centre of distribution, and the pressure there will be maintained as nearly constant as possible; and each motor or group of motors will be run on separate distributors, the areas of which will be so calculated with reference to their length and to the maximum or average current, that the maximum or average fall of pressure will be fixed between reasonable limits.

This brings us to the feeder system (*b*) shown in Fig. 29. As before, *a* represents the dynamo, or say the power station if there be a number of dynamos in parallel, *a b* represents the transmission mains or feeders, *b* the centre of distribution and the point at which the pressure is to be maintained constant; and *c*, *d*, *e*, *f* and *g* severally represent motors at the ends of distributors *b c*, *b d*, *b e*, *b f*, and *b g*. Let the pressure of distribution be fixed at 300 volts at the point *b*, and let the feeder efficiency at full load be 10 per cent. *i.e.* a drop of 30 volts is permitted along *a b*. The pressure at the power station will be 330 volts at full load, and will fall as the load is decreased until the smallest output is reached, when the pressures at the station *a* and the distributing centre *b* will be approximately the same. The fall of pressure in each of the distributors may be regulated according to the class of work

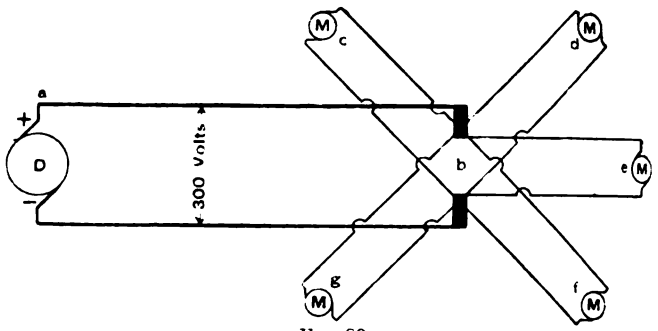

FIG. 29.

and regularity of speed required—an average drop of about five per cent. will usually be permissible for power work. The efficiency of the entire line will be therefore say, 85 per cent. under these assumptions; but it must be remembered that the conditions selected are entirely arbitrary, and the economic limitations discussed in previous sections have not been taken into consideration in any way whatever.

The next practical point bears on the limiting distances through which power can be efficiently transmitted. The two-wire feeder and distributor system (Fig. 29) has already been examined, and it is clear that the distance of transmission is practically fixed by the pressure of supply. Now the pressure of the distributors cannot be greater than that permitted by the conditions of supply to the consumers—500 volts will probably be the maximum pressure. But there is no such restriction to the pressure between the feeders; and hence

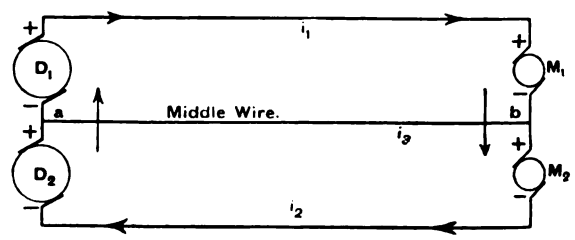

FIG. 30.

the *three*-wire feeder system shown in its simplest form in Fig. 30 is evolved. In this, essentially, two dynamos are coupled in series across the feeders, each giving, say, 500 volts and 50 amperes, and thus making a line pressure of 1,000 volts.

At the end of the feeders two suitable motors are also coupled in series, and a third wire is coupled to the junctions of the dynamos and that of the motors as is indicated in the diagram. The path of the current, when the motors are equally loaded, is shown by the arrow heads, and it is seen to be entirely confined to the machines and the two outer conductors, the middle or third wire carrying no current. But if one motor absorbs more current than the other, the difference between the two currents will pass through the centre wire. Let i_1 be the current in the circuit D_1 M_1; i_2 that in the circuit D_2 M_2; and i_3 that in the middle wire. Now when $i_1 = i_2$, then $i_3 = 0$; and also when $i_1 > i_2$, then $i_1 - i_2 = i_3$. When i_2 is zero, *i.e.*, when M_2 is not running, then $i_1 = i_3$ and the middle wire has to carry the whole current in the circuit D_1 M_1. In such a case it is not advisable to make the middle wire of less section than the two outer ones; but if M_1 and M_2 each represent

Digitized by Google

a group of motors, it is reasonable to assume that full load on one circuit and no load on the other will be unlikely to occur at the same time, and, therefore, the middle wire will have to carry only the difference between the two currents. In practice, with a load of lamps, it is found to be sufficient if the area of the middle wire be half that of one of the outer wires. And it should be recollected that if the distributing centre be a large one it will be provided with suitable switching arrangements for transferring part of the load on the distributors from one circuit to the other, as may be necessary to secure a proper balance, and to keep the current in the middle wire as small as possible.

Assuming the load to be so arranged that it will be generally divided nearly equally between the two circuits, and that full load will never be on one and no load on the other, it will be safe to follow lighting practice and to make the middle wire of one-half the area of the outer ones. This will permit a difference of load in the two circuits sufficiently wide to meet the requirements of practice. Now it is seen that, for the same output from the power station the three-wire system requires twice the pressure and half the current necessary in the simple parallel systems shown in Figs. 27 to 29. And if the same gauge of wire be used the weight of copper in the three feeders will be 25 per cent. greater than that of the two, being in the ratio of 5 : 4; but since the middle wire is nominally idle and the outer feeders carry only half the current in the two-wire mains, it is clear that for equal conductors, output (twice

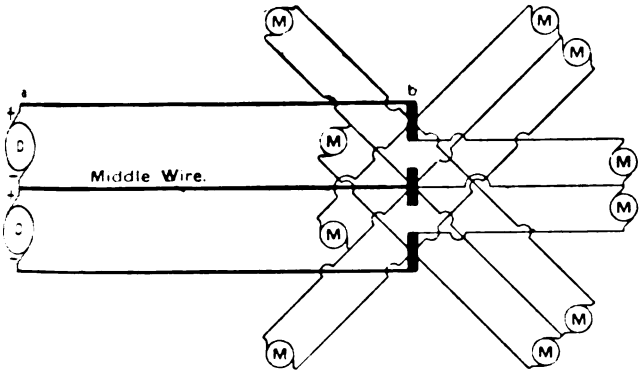

Fig. 31.

the pressure and half the current), and distance (between points *a* and *b*), the power lost in them will be only one-quarter with the three wires as with the two wires, and the fall of pressure will also be only half as great. For *equal conductors* and the same drop of pressure, the three-wire may be therefore twice as long as the two-wire system ; and for equal line loss or feeder efficiency and the same percentage of drop, four times as long. And if the relative weight of copper for *equal lengths* be considered, since the area of each outside conductor is one-half, and of the middle conductor one-fourth, of the area of either conductor in the two-wire system, the ratio of total weights will be as 5 : 8, showing a net saving of 37½ per cent. in favour of the three-wire system.

This system is evidently capable of extension, for let four wires be used and coupled to three dynamos and three motors, the pressure may now be 1,500 volts over the outer feeders and the current only 33·3 amperes ; and if the outer mains have the same section as before, the distance through which the power may be transmitted with the same drop is again raised by 50 per cent., or is three times as great as that with the parallel system, and the weights of copper for equal lengths are as 1 : 2. At Manchester a five-wire system has been erected for lighting to the specifications of Dr. J. Hopkinson. The outer mains are at 420 volts approximately, and between each of the pairs there is a pressure of 105 volts. Such a system is not likely to be used for the feeders of a power plant.

The three-wire system is applicable to the distributors as well as to the feeders, and is an important means of reducing the fall of pressure in the distributing net-work (*see* Fig. 31) which represents the disposition of feeders, distributors, and motors. It is apparent, however, that the three-wire feeder system, as well as the two-wire, ultimately reaches a limit beyond which it does not pay to transmit power ; for though the pressure may be raised almost indefinitely as regards the feeders, it is not so with the distributors—500 volts being probably a maximum for the supply service even in power work.

The next step is a pair of high-tension feeders coupled to a *regulator*, which may be a motor having as many armatures on the same shaft as there are sub-circuits, and feeding each pair of distributors at the desired pressure. These sub-circuits may be coupled on the multiple-wire principle. The general idea is shown in Fig. 32. In this diagram the armatures are sketched as if they were independent of each other. But in practice they are rigidly coupled or built on one shaft and essentially run in magnetic fields of the same strength and direction (or they may run in a common field). The arma-

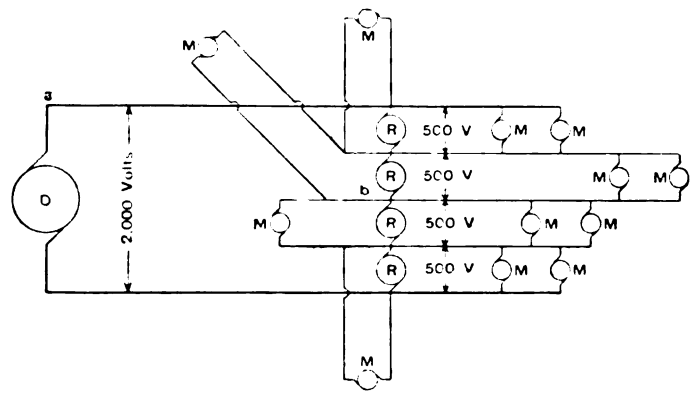

Fig. 32.

tures are of identical construction, and their internal resistance is made as low as possible. The field excitation is preferably supplied from an independent source such as accumulators, which may be charged in parallel across one of the sub-circuits at suitable times. Normally, when the load is equally divided between the sub-circuits, the four armatures absorb just sufficient current to overcome friction. But when one of the circuits takes more current than the others the armature in shunt to it will tend to lag. And the armatures in parallel with the other circuits will resist this alteration, and being coupled to the lagging armature will spend power in keeping the speed constant. Thus the lagging armature will be driven as a generator and supply the increase of current to *its* circuit, and the necessary power for the increase of torque will be supplied from the generating station. The degree of regulation attainable with this device depends on the internal

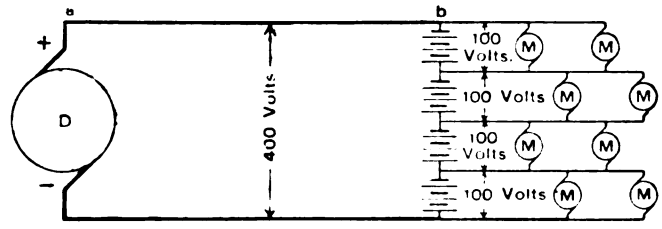

Fig. 33.

resistance of the armatures ; and it can only be efficient when the pressure lost over the armatures is negligible. The regulator principle is capable of considerable modification, and is likely to be used in one of its many forms for lighting in cases where the feeders are of great length.

Secondary batteries have already been used with undoubted success, in connection with three-wire distributors for central station work, by Mr. Crompton and others. The method is illustrated in Fig. 33. It will be apparent that the secondary battery acts as an accumulator as well as a regulator, and can be arranged to store up energy during periods of light load, which will be available for temporary outputs exceeding the rated engine and dynamo power ; and also in many cases the accumulators can deal with the small loads during parts of the early morning, and the steam plant may be shut down for that period.

ELECTROLYSIS AT DEFINITE ELECTRICAL PRESSURES.

BY BERTRAM BLOUNT, F.I.C., F.C.S.

Since attention was recently called to the relation of the decomposition of salts of different metals to the pressure of the current used in their electrolysis, and to the methods of separation that could be founded on this relation—facts which, as indicated in these columns, are in no way new, but merely apparently novel on account of their persistent neglect—considerable activity has been displayed in extending and defining the knowledge thus exhumed. The latest contributor to the subject is H. Freudenberg, writing in the *Zeitschrift für physikalische Chemie*, the gist of whose observations, together with the comments they suggest, may be set down as follows:—

The view now fashionable, that a solution contains the dissociated ions of the salts present therein, involves the adoption of the belief that electrolysis of such solution can be effected by a current of indefinitely small pressure, the sole function of the current being dirigent. The data upon which this theory depends are both too limited and too particular to warrant its being regarded as more than a working hypothesis, of merit, indeed, but in wholesome competition with its kind for audience and acceptance. Moreover, it applies strictly to solutions of infinite dilution, and there is reason to suppose that as the usual limits of dilution are approached, other forces, nearer in their nature to those involved in ordinary chemical reactions, modify or abrogate the dissociation of the ions of dissolved salts. Taking, then, the more generally applicable hypothesis that there is a critical pressure of decomposition for each electrolyte, we are confronted with the fact that for the smooth electrolysis of a dissolved salt the pressure employed must be below that at which the electrolysis of its solvent begins. In the case of water, the commonest solvent, this pressure has a value of about 1·70 volt when the substance in solution is an acid or a base, but another figure is found for solutions of neutral salts Thus the value for a solution of sulphuric acid is 1·76, for caustic potash 1·67, for potassium nitrate 2·16, for sodium sulphate 2·21, and for zinc sulphate 2·35. The determination of the decomposition of water itself, when uninfluenced by the presence of dissolved substances, is difficult on account of the extremely high resistance of approximately pure water, and the doubt whether any observed result may not be due to a trace of impurity in solution. However this may be, a practical application of the difference in behaviour of salts of various classes is immediately possible.

Metallic salts, such as are commonly electrolysed, have been long tacitly, though not explicitly, divided into three groups: those from which the metal cannot be separated by the electrolysis of their aqueous solutions, *e.g.*, the salts of the alkalies, alkaline earths, aluminium, and chromium; those from which the metal can be deposited as peroxide at the anode, such as lead, manganese, and thallium; those from which the metal can be thrown down at the cathode, which include all that have been investigated in this connection with the exception of the members of the first two classes. It is among these latter that separations by variations of the pressure of the current used in decomposing their salts can be effected.

For experimental purposes, where a fairly close measure of the volts employed is required, a thermo-electric battery presents the advantage of yielding a nearly constant pressure, so that for the work now under discussion the time-honoured Daniell and Bunsen were set aside in favour of a Gülcher battery. Needless to say, the futile practice of reporting the volume of "bang-gas," evolved in a voltameter in circuit with the decomposing cell, was not adopted, as a measure of the total energy expended was not required, but only one of the intensity of that energy. It is highly desirable that experimenters would once for all abandon a method of stating their results which is a mere anachronism nowadays. Precipitation was effected in platinum dishes exclusively, so that no complications from independent action of the electrolyte might arise. The following are some of the separations attained by these means.

Silver was separated from copper in a solution of the nitrates of the two metals, containing free nitric acid, with a current having a pressure of 1·3 volt. Under the same conditions silver only was thrown down from a solution containing bismuth. With 1·7—1·8 volt silver was separated from arsenic, and at 1·2—1·3 volt from antimony, and at 1·6 volt from cadmium. Similar separations were obtained of silver from zinc and platinum, and mercury from copper, bismuth, arsenic, antimony, and cadmium, as well as of copper from cadmium and arsenic at 1·85—1·9 volt. It is noteworthy that the pressure needed to precipitate copper from most of its solutions is 1·8 volt, while from a solution containing oxalic acid 1·1 volt suffices. This observation gives cause for reflection. It has, of course, long been recognised that the deposition and separation of most metals succeeds best from particular salts, which are generally prepared *in situ* by adding to a solution of the sulphate, nitrate or chloride of the metal, an alkaline salt of the particular acid, *e.g.*, oxalic, hydrocyanic, acetic, &c., the compounds of which, with the metal to be deposited, is found best fitted for electrolysis, but hitherto little systematic study has been directed to the determination of the precise pressure needed to deposit a given metal from each of the salts which are found to yield it in a reguline form fit to be weighed. When a complete series of figures of this kind has been worked out, methods of separation by electrolysis, both for analytical and industrial purposes, will be greatly improved. Such data will be useful, not only for metals of the class that can be deposited from the aqueous solutions of their salts with the stronger acids, but also for others like iron, nickel, and cobalt, which have to be treated in alkaline solution as the pressure needed to decompose their ordinary salts in acid solution lies above that necessary for the electrolysis of water, inasmuch as the critical pressures for those double salts, *e.g.*, those of nickel and ammonium, and double cyanides, can then be utilised for the separation of members of this group after they have been obtained free from the more easily deposited metals already spoken of.

It will be seen from this account that progress is being made in the science and practice of electrolysis on thoroughly sound, because quantitative, lines. The days when disjointed qualitative observations of electrolytic phenomena were tolerated and even deemed acceptable are gone for ever, as completely as they are in the field of purely electrical research.

THE SALÈVE ELECTRIC RAILWAYS.

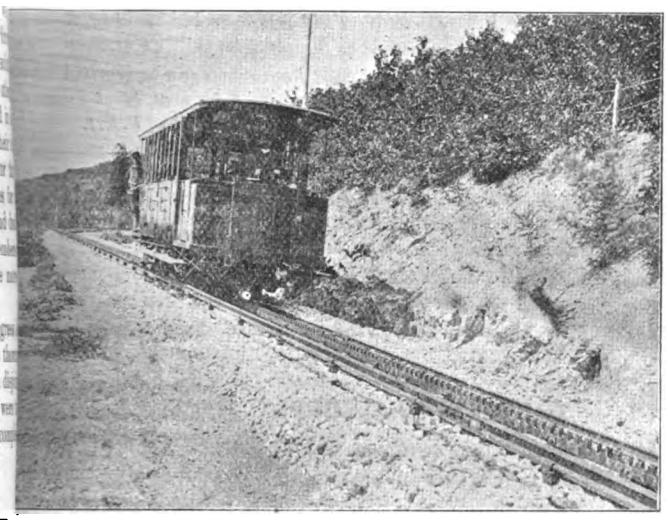
The Salève electric railways were the first mountain railways, that is to say, those utilising the rack, on which motive-power was supplied by electricity. They are intended for establishing rapid communication between Geneva and the different villages along the Salève, Mornex, and Monnetier, well known health resorts; and, moreover, for carrying tourists at Treize Arbres to view the mountain panorama. From the plain, two lines start; one from Veyrier, the last village on Swiss territory in that direction, goes to Monnetier, passing along the picturesque Pas de l'Echelle; the other, more specially made to serve Annemasse, has its origin to Etrembières, and goes round the Petit Salève, passing through Mornex, which has two stations, and arriving at Monnetier, where the two lines meet. A more alpine appearance is then assumed, the slopes are steeper, and habitations are no longer met with. The terminus is reached in 45 minutes, either from Etrembières or from Veyrier. The difference of level is about 900 metres on a length of six kilometres. It was consequently impossible to utilise ordinary adherence rolling stock, and it was decided to use the Abt rack, with a single rack on the lightest grades, and a double one when the grades become heavy, that is to say, on most of the length. Metallic sleepers are used, and are strongly fixed in a bed of thick broken stones. The rails, which are of the Vignoles type, weigh about 20 kilogrammes per metre run. Sleepers, rails, and racks are electrically connected together, and serve as conductor for the return current. The connection between

Digitized by Google

e different parts of rails is ensured by copper strips carefully ldered at each end.

The current is brought along the line by another Vignoles il with the plane face upwards. This rail is maintained at out 50cm. above the ground by means of iron rods fixed at e extremity of the sleepers. These rods support at the per end a strong porcelain insulator. On this insulator, but parated from it by a piece of lead sheet, is fixed a metallic llar supporting the rail. The different sections forming the nductor are also electrically connected by means of copper ips, and this conductor is totally interrupted on short ngths, in order to leave a certain freedom for expansion and ntraction. The arrangement is such that the connection th the rail still takes place by one at least of the two ntacts provided on each car, the surface of these contacts ing made large enough to carry the whole current required the car without overheating.

The generating station is placed on the Arve, near the conence of the Viaison. A good mill site was chosen at a very arp curve of the river. By excavating a short tunnel for e tail race, a fall of three metres was created, without any ed for constructing costly dams. The volume of water ailable averages 35 to 40 cubic metres per second. The ation is located on the right bank of the river, and is of suffint size to accommodate three turbines and dynamos. At



Salève Railway; showing Car, Rack, and Insulated Rail.

e present moment two only are fitted. The turbines are rtical engines, built by Rieter, of Winterthur. They are of e Girard type with partial injection. At a speed of 45 revotions per minute each of these can develop a maximum of 0 H.P. and drives directly a dynamo.

The dynamos, which are on the Thury system, have each elve poles, and are arranged to develop 1,000 H.P. at 180 relutions per minute. These machines are separately excited, eir field winding receives normally a current of 45 amperes. ne weight of this winding is 1,450 kilogrammes. The magtic field generated in the air-gap has an average intensity of 500 C. G. S. lines. The cores are made of wrought iron and e pole-pieces of cast iron. The internal boring is 2,500mm.

The armature, which is of the hollow drum type, bell shaped, formed by uniting segments of iron sheet and insulating by per and varnish. The width of the armature is 15 centietres, and its depth 45 centimetres. It is wound with the hury multipolar winding, composed of 451 coils giving a eight of copper of 178 kilogrammes. The collector has a ameter of 1·8 metres, and is composed of 451 sections of hard awn copper insulated with mica. The current is collected means of 48 carbon brushes disposed in sets of four on elve arms. The machine delivers 600 volts and 280 amperes 45 revolutions per minute. Its weight is 18 tons.

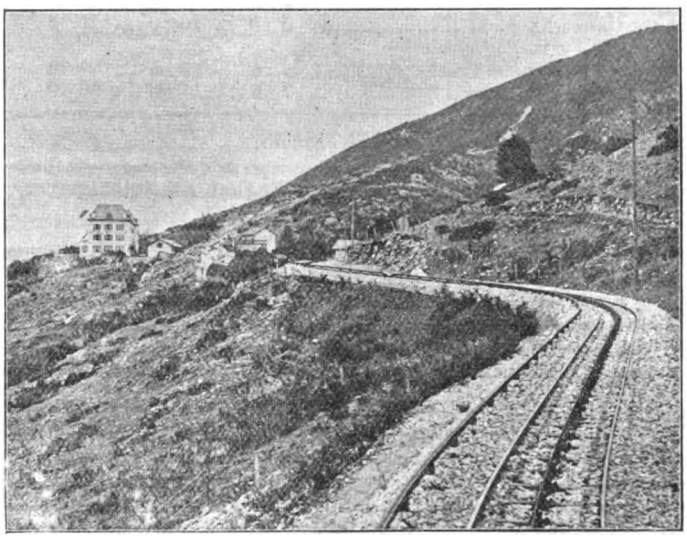
The current required for the excitation is supplied by a ecial dynamo driven by a 15 H.P. turbine. The regulation the voltage on the line is obtained by varying the excitation, that variation being effected automatically, by the action of a regulator acting upon the excitation, and by the action of the main current, which passes through a part of the exciter's field winding, and tends to increase its magnetic field as the current on the line increases. By this means the voltage is maintained fairly constant on the line, whatever may be the variations of current.

Where the line leaves the generating station lightning arresters are placed, to preserve the machines and apparatus. These arresters, consisting of condensers and impedance coils, are simple and effective.

The conductors connecting the generating station and the line are 1,800 metres long, and are supported on wooden poles. Each of them has a sectional area of 430 sq. mm. They are connected to the line at equal distance from Veyrier, Etrembières, and Treize Arbres.

The cars contain 40 seats and are supplied with two 40 H.P. motors. These motors revolve at 600 revolutions per minute, are electrically connected in parallel, and gear on the rack by means of a double reduction gearing, which reduces the speed in the ratio 13 to 1. According to the grade, the cars run between 1·5 and 3 metres per second.

The current is collected on the rail by means of two contacts on each side of the car, only one pair making contact at



Salève Railway; showing Arrangement of Rails and Rack, and Steep Gradients in the Distance.

once. These gun-metal contacts are very massive, and are provided with springs, ensuring a good connection in spite of vibrations. The return current passes to the rails by the wheels and the truck of the car.

Before reaching the motors, the current has to pass through lightning arresters and resistances, by means of which the speed may be regulated and a gentle start secured. The commutator, which is controlled by the driver, is provided with contacts, by means of which the resistance in circuit may undergo wide changes. Another apparatus permits of reversal of rotation of the motors; and an ammeter placed near the driver gives indication of the behaviour of motors.

The current required for lighting the car is supplied by a shunt on the main current. Five lamps are used, all connected in series with a suitable adjustable resistance.

For cars running on grades of 25 per cent., and even 30 per cent., the question of supplying good brakes was of the utmost importance. Three methods have been tried.

The first one consisted in changing the direction of the current in the motors, so causing a sudden stopping. It is not much employed on account of the violent shocks it occasions. The second one consisted in using the motors as generators under the effect of the declivity, sending their current through the resistances. The third one is a mechanical brake provided with a circulation of water. The different stations are connected together, and with the generating station, by telephonic lines.

STEEL-PLATE PORTRAITS

Of Willoughby Smith; W. H. Preece, F.R.S. (President of the Institution of Electrical Engineers); Michael Faraday; Sir John Pender, G.C.M.G., M.P.; Sir William Thomson, F.R.S. (Lord Kelvin); C. H. B. Patey, C.B.; Dr. John Hopkinson, F.R.S.; Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S.; Prof. von Helmholtz; Prof. W. E. Ayrton; Lord Rayleigh, F.R.S.; Cyrus W. Field; Werner von Siemens; and Sir James Anderson, have been issued as Supplements to "THE ELECTRICIAN."

Copies of these admirably-executed Steel Engravings can be supplied price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price 4s. 6d., carriage paid (U.K.).

NOW READY.

Volume XXX. of "THE ELECTRICIAN," price 12/6; post free, 13/6 abroad carriage extra.

Cases for binding Volume XXX., price 2/0, post free, 2/3.

The Publisher is able to supply a set of the Volumes of "THE ELECTRICIAN" complete except for three Nos. Price on application.

THE ELECTRIC SUPPLY OF TIME.

It is so customary to designate as electric *light* companies the various undertakers of electric power supply that there is some risk of our forgetting that the scope of these undertakings is a far more extensive one than the name connotes. Indeed the limitations imposed upon so-called electric light undertakers are practically nothing more than the supply of ampere under a specified condition of volts. Without giving way to the wild speculations of popular science, which sees in electric supply the "open sesame" to a physical millennium we may recount numerous applications of public current supply to other purposes than lighting, which are either now realised or are commercially potential; and the gradual extension of which is ever tending asymptotically to render the term "electric light company" a complete misnomer. Already we find publicly-supplied current employed to develop mechanical power for a wide variety of purposes, and one of the latest developments is the use of an electric supply for regulating a system of clocks. This last application which occurs in Berlin, where the local electric supply company has adopted, for the benefit of its customers, a system of electrically-controlled clocks, invented by VON HEFNER ALTENECK, yet another instance of the comparative facility with which the public outside the United Kingdom can be induced to take up new ideas of this kind. Climatic conditions perhaps render impracticable the floating of a company to supply London like St. Louis, with ammonia for cooling in summer, and with steam for heating in winter; and other equally solid reasons would no doubt account for the poor outlook that there is in this country for electric motors and electric cooking. Even

Digitized by Google

the measure of success which has attended the efforts of the London Hydraulic Power Company is relatively small, and the English municipality which should propose to spend the ratepayers' money, and at the same time assist the day-load in a microscopic manner by erecting electrically-controlled clocks, as was once, and may be still is, done in Brussels, at nearly every street corner, would inevitably succumb to the combined indignation of ratepayers and watchmakers. In short, the day when the sturdy individualism of our London public clocks, not to mention that of the so-called domestic time keepers, will be disciplined beyond recall by timely impulses from Deptford, is as yet far distant.

Although in Berlin they have now got as far as to employ the electric current in dispensing the most important of the three fundamental physical quantities, the conception of time is in reality very far from simple; it arises from the sequence of events, and depends on the observation of intervals between successive phenomena, and it is worthy of notice that this complete dependence of the time-consciousness upon "something going on" would render it absolutely impossible for us to detect a temporary stoppage of the universe, or in any way to gauge the period during which it remained absolutely passive. Newton, it will be remembered, in his empirical definition of mathematical time, conceived it to flow at an absolutely steady rate, unaffected by the speed or slowness of the motions of material things or by our states of consciousness. Floating, as it were, at equal distances on this steady stream of time are the indications by which we arbitrarily measure it, and chief among these we notice that fictive quantity, the mean solar day. The duration of the mean solar day, as our astronomical text-books will tell us, is determined by the interval between two successive meridian transits of an ideal or imaginary sun. Owing to this basis of time measurement there is a definite geographical variation of the instant of any particular transit. In devising a system of time, then, the choice lies with one of three courses: either to determine the commencement of the day at each place by the transit over the meridian of that place, and thus to adopt local time at each locality; or to fix upon one particular line of longitude as the standard meridian for every locality, and thus to adopt universal time; or else to combine the two systems. If we were rooted to the ground like trees, local time would be the most valuable; if we could travel from England to America in a fraction of a day, universal time would serve us best. In the present state of evolution and civilisation we compromise and adopt the last-named course. Now, the institution of a central time bureau implies the existence of some connecting link between the bureau and every timepiece within the boundaries of its influence. No clockwork mechanism is infallibly regular in its action; and few of us but forget to wind it up occasionally. The existing common link is crude, and consists mainly in setting a timepiece "right" by another which is equally liable to be wrong. The ideal link would consist in an actual regulating force applied by the central clock to every timepiece. Only in a very imperfect degree has this ideal been realised. At Greenwich there exists a mechanism which propagates an electric current to various points in London and other cities, which, at prearranged intervals, will wipe out the accumulated errors of the clocks at these several points; but, with our usual slowfootedness, the system of electric control from Greenwich has not been extensively used.

In the system now in vogue in Berlin the clocks are both propelled and controlled by the current from the electric power central station. Each clock is provided with a mainspring, which conserves sufficient energy to keep the clock going for twelve hours; but, in the normal state of affairs, this mainspring is kept fully wound up by an electromotor of simple construction. The large capacity of the spring is intended to obviate the disadvantages, which would arise if the clock depended on the state of the house fuses. Every morning at exactly 5 o'clock, there is a 10 per cent. fall of pressure on the mains, the object of which is to bring the regulating gear into action and correct the time-reading of the clock. This gear is only affected by variations of pressure at about 5 a.m., so that there is no liability at other times of a sudden load on the mains putting the hour hand of every clock to 5. Why 5 o'clock in the morning is the hour chosen for the purpose of regulating the clocks it is not easy to discover. True, there are but few lights on the mains at this time; but it is probable that these are on important service. Five a.m. is the hour when vitality is at its lowest ebb, when disease is most active, when suicide is most common, and so on. Is it for these reasons that a 10 per cent. drop of pressure is inflicted on the lamps at 5 a.m., when noon would seem to have every advantage in its favour? The essential objection to the Berlin system is that it restricts the area of control to very much narrower limits than the area over which the particular system of commercial time operates. The range of an electric supply company is at best a large town or a slice of a large city; while the range of any system of commercial time extends many scores or hundreds of miles on either side of the meridian. Nevertheless, the Berlin system has its merits, for it offers to the consumer time which, if not perfect, is at any rate as perfect as his neighbour's, and it brings to the supply company a class of consumer which requires a steady, even though small, supply of electric power.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 473.)

In working with French or German glass, which does not contain lead, no great attention need be paid to the flame, and any part of it may be used. As, however, lead glass is used almost always in lamp-making, it is necessary to take care that the flame is a suitable one, called sometimes a "clean" flame. That is to say, it must be one in which the "reducing" and the "oxidising" parts are clearly defined and are not mixed up. Figs. 24 and 25 show the forms of the cannon and the pointed flames respectively. The "reducing" flame is that part marked B. It contains an excess of carbon, while in the "oxidising" flame, C, there is an excess of oxygen. These different parts of the flame can be easily distinguished by their appearances. The hottest part of the flame is just at the junction of B and C, at the tip of the point of B in Fig. 34.

In working with lead glass, the oxidising part C can alone be used. If the glass is held in B, some of the lead is immediately reduced to the metallic state, and colours the glass black. When this takes place it is at once seen by the lead appearing as a bright red opaque patch on the otherwise nearly transparent glass. If allowed to cool, the patch will be found to be black. When this patch of lead appears, it can easily be oxidised again by holding it further away in the C part of the flame. This, however, can only be done if the patch is superficial. If the lead has been reduced much below the surface, it is impossible to get the glass clear again. The

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

reason for being so particular about the inner or wind tube of the blow-pipe is that a tube which is irregular in any way will impart its unevenness to the air blast, so that the oxidising and reducing parts of the flame are all mixed up, or rather there is no oxidising part. Blow-pipes with metal wind tubes, which may be purchased ready made, are generally unsuitable for lead-glass working on this account.

The blow-pipe is fixed on the table about four or five inches from the edge, and pointing directly away from the operator. The table should be covered with a thick sheet of asbestos, and this should be painted black, as the flame can be seen much better against a dark background. The glass-blowing table should not be brilliantly lighted, and the light should come from above, or from the sides, and not from in front of the operator. If there is too much light, it is difficult to see the flame, or, at any rate, the oxidising part of it, which is almost entirely non-luminous.

There is one objection to the cannon form of blow-pipe for large flames. It is very noisy. In a room with a number

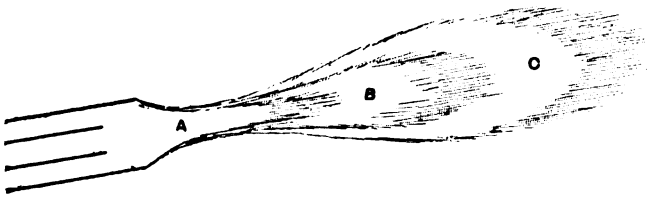

Fig. 24.

of them at work it is a matter of some difficulty to hold any conversation, on account of the powerful roar which they make. The small pointed flame (Fig. 25) makes, however, no noise whatever, and for this reason it is better to use a compound blow-pipe made up of several small noiseless flames. This may be accomplished by fixing three or four blow-pipes giving such flames side by side, and directed so that the tips of the flames meet each other. To obtain a greater heating power, an equal number may be arranged opposite to the first set, in the reverse direction, so that all the tips of the flames meet in the centre of the space between the two sets of blow-pipes. In this way is produced an excellent and perfectly quiet blow-pipe flame, which gives a more even heating, the glass being heated on both sides at the same time, though this is not always an advantage. Such an arrangement, however, is only applicable to work which does not require a varying flame. It is suitable for sealing in

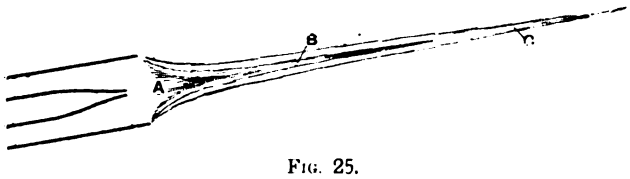

Fig. 25.

filaments, though the pump-maker could not work with it entirely. It is certainly an advantage to have the sealing-in room quiet. Six or eight cannon blow-pipes set up together in the way just described is, however, a rather clumsy arrangement. A better plan is to use blow-pipes of the form shown in Fig. 26. A is the gas tube, B is the air tube, each of which is provided with a stop-cock. At the top A terminates in a hollow burner, through which the gas passes by a number of small holes. The air tube B terminates in a glass nozzle C. The gas issuing from the top of A having been lighted, the stop-cock in B is turned, with the result that the air coming from C blows into the luminous gas flame and makes it assume the pointed quiet type of blow-pipe flame. Six or eight of these blow-pipes may be arranged so that the flames are combined together, as shown in plan in Fig. 27. The six pointed flames burn no more gas than the single cannon flame suitable for the same work would do; probably they burn less. The compound form is, of course, more costly in the first instance. There are stop-cocks, controlling both the air and the gas of the whole six burners, so that in case of any increase or decrease in the pressure of either, it is not necessary to alter the whole six or twelve cocks; in fact, when the stop-cocks in the pillars are once set properly they should not be again disturbed.

It is essential that the glass-blowing room be free from draughts, as a slight draught will blow the flame to one side, and render working difficult. As a consequence of this, the state of the atmosphere in a glass-blowing room with a number of blow-pipes working is often distressing to anyone but a glass-blower. There is no reason why a glass-blowing room should not be lofty and well ventilated, without any inconvenient draughts, but it is seldom the case. The author, not long ago, had an opportunity of going over a new lamp factory, the building having been constructed for the purpose, and was surprised to find that even under such circumstances the glass-blowing room had a very low ceiling, and no means of ventilation whatever. The quantity of gas used by a blow-pipe is very considerable, and the ventilation should, of course, be in accordance therewith.

Each glass-blower may, by means of a foot bellows, pump the wind for his own blow-pipe. This method has an occasional advantage in enabling him to vary the pressure, and, therefore, the form and heat of the flame without having to turn a cock. It seldom occurs, however, that one hand cannot be spared for an instant for this purpose.

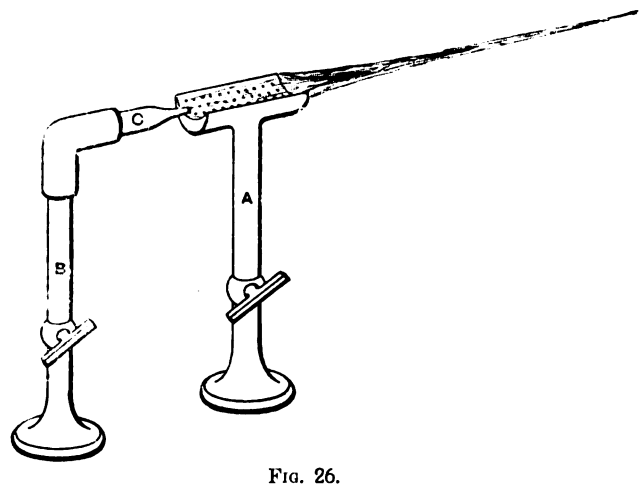

Fig. 26.

The disadvantage of a foot bellows is that the glass blower cannot sit so comfortably or steadily, both important considerations in glass-blowing, when he has to keep one foot pumping up and down all the while. Moreover, the wind is apt to run out at a critical moment. If a foot bellows is used, it is best to use a much larger one than the ordinary laboratory form, and to have it fixed underneath the table with a large air reservoir, in order that the blast may be steady, and not go up and down with each stroke. The bellows and reservoir should be large enough that a single stroke will supply the blow-pipe for some minutes. Such an arrangement, however, does away to a great extent with the advantage mentioned of being able to vary the force of the blast with the foot at any moment, which can only be done with a bellows of small capacity. In a factory where a large number of blow-pipes are required it is necessary that a supply of air be laid on so that the glass blowers do not require separate bellows. For this purpose, a mechanical pump with a single cylinder driven by power answers very well. The air is forced into an iron tank with a blow-off valve. The pressure may very well be five or six pounds to the square inch, and the blast will be perfectly steady if the reservoir is large enough. The force of the blast is, of course, entirely under control by the screw cocks on the blow-pipes. With an ordinary foot bellows the pressure is only a small fraction of this amount, but a much larger pressure in the pipes works perfectly well as long as the rate at which the air is admitted into the flame is under control. The air should be taken from the pump into the side of the reservoir, the bottom of which should be of such a form that any water inside may drain towards one

Digitized by Google

part where a cock can be placed by which it can be let off. The delivery pipe should be led off from the top, so as to be as dry as possible. In damp weather there is always water condensed in the reservoir, and if it gets into the pipes it may cause trouble at the blow-pipes. Instead of a pump, a fan may be used. Fans, however, as usually constructed, are adapted for delivering large quantities of air at a small pressure, and are, consequently, unsuited for supplying air through long lengths of small piping. As a rule, they require a very high speed, and are very noisy.

As lamp bulbs blown from glass tubing have not altogether gone out of fashion the method of making them will be described. The cannon form of blow-pipe with the noisy flame is the best to use for this purpose. The size of the glass tube from which the bulbs are to be blown will be selected according to the size of the bulb which is required. For an ordinary sixteen-candle power size it will be about $\frac{3}{4}$in. in diameter, and about $\frac{1}{16}$th in. or rather more, in thickness. The tube must be quite clean inside and out, as any dirt may get burnt into the glass, so that it cannot be removed. The glass tubes are usually cut into lengths of about 3ft. The glass blower takes one of these, and sitting at the table with the blow-pipe just in front of him, he adjusts the size of the flame, using more gas at first than he requires for softening the glass, making thereby a flame much larger and not so hot as he will ultimately require. He then holds the glass tube with his left hand, so that one end of it is in the flame at some distance from the blow-pipe, at the same time turning the tube round and round so that it shall get heated evenly. The heating must be started gradually in this way, or the tube may crack.

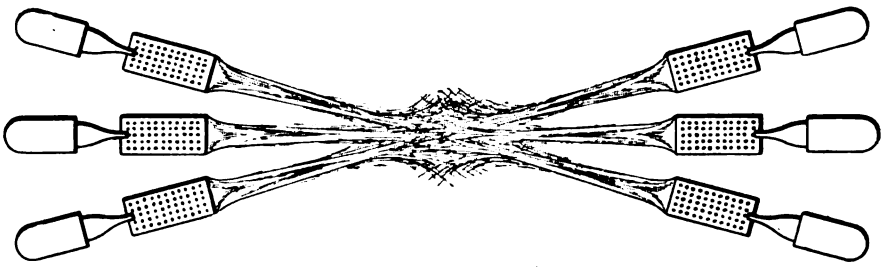

Fig. 27.

If the tube be a thick one it will be necessary to turn it round and round at a point beyond the flame altogether, so as to get it very gradually heated before it is brought into the flame at all. As the tube becomes heated the gas is turned down, thereby reducing the size of the flame, and making it hotter. The end of the tube, constantly being rotated, is brought into the oxidising part of the flame, and it soon begins to soften. When this occurs the glass blower presses the ends of the tube inwards with the tail end of a file or other convenient instrument, so that the sides touch one another. He then melts on a short length of small "cane" or "rod" glass. Having done this, he will heat the tube a little lower down, and when it is soft he will take it out of the flame, and, by means of the piece of cane glass, will draw out the heated part of the tube for 8 or 10in. or so, as shown in Fig. 28 (B). The part drawn out will be narrow and thin. When the tube on which the glass blower is working is long he cannot conveniently hold it up and work it at the same time. A rest must therefore be provided to hold one end of it. If the end is allowed to lie on the table it will roll along as the tube is rotated. The rest must therefore carry a groove or notch in which the tube can turn without rolling along. Having drawn out the end of the tube, the piece of cane used for the purpose is no longer required and may be detached. The tube is then heated about 3in. lower down and drawn out as before for 15in. or so, C, Fig. 28. This is done by means of the first piece drawn out, which, being thin, quickly cools enough to allow of handling. The tube is then cut at the centre of the narrow part of the second drawing out, leaving a piece of the original tube about 3in. long drawn out at each end into a small tube, D. The glass is cut by first scratching it with a file and then pulling it, when it will part at the scratch. The process of drawing out and cutting off is then repeated until the whole of the tube has been converted into pieces similar to D. Each of the pieces will make a bulb. The next operation is to close up one end by heating in the flame. This is easily accomplished, as the glass will close up of itself as soon as it becomes soft. When

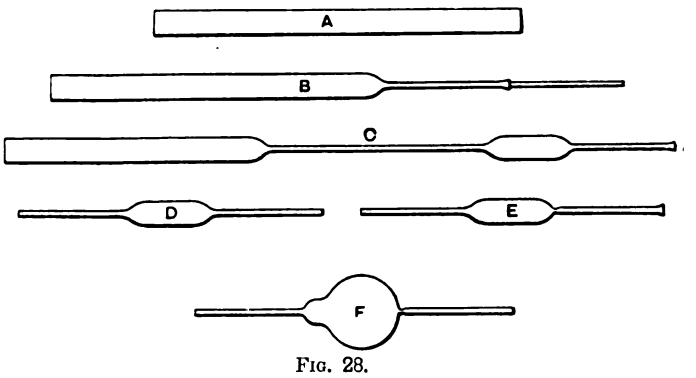

Fig. 28.

this is done, the narrow tube, which has not been closed, is heated close to its junction with the full-sized tube so as to make a contraction in the bore, E. This is the point where the lamp will be eventually sealed up after pumping. Nothing remains now but to form the bulb. For this purpose a rather larger flame is required, and is made to play upon the thick part of the tube, E, rather nearer to the contracted end than the other. As the glass softens it caves in all round, and the glass-blower pushes the smaller tubes inwards so as to get the soft glass into a smaller space, and so get it better covered by the flame. When it has attained the exact degree of softness, which is ascertained as much by the feel as the appearance, he takes it out of the flame, and holding it with the open end to his mouth in a horizontal position and quickly rotating it all the while, he blows into it with a series of short quick puffs, thereby blowing out the softened glass to any required extent forming a bulb, F. The bulb can be made of any shape according to the way the soft glass is manipulated and blown into. Success in blowing a bulb depends on the even heating of the glass and skill in manipulating it while it is being blown into. It takes a good deal of practice before a good symmetrical bulb can be made with certainty. Beginners invariably make one side larger than the other. If a large bulb is to be made from tubing a quantity of glass must be run together so that it is very thick at the place where the bulb is to be blown. This is accomplished by pressing the tube lengthways towards the softened part, thereby bringing in more and more glass into the flame. The exhausting tube of the bulb F should be closed up as soon as the bulb is finished to prevent dust from getting inside. Bulbs blown from tubing as described have this exhausting tube already attached. Pot bulbs, however, have no such tube, and one must consequently be joined on. This has to be done before the filament is put in, as the tube is necessary for holding the lamp during that operation. Tubing of the required size, about $\frac{1}{8}$in. diameter, is cut up into lengths of about 6in. An indiarubber cap is slipped over the neck of the bulb to make it air-tight. The end of the bulb

Digitized by Google

where the exhausting tube is to be attached is then held in the blow-pipe flame, being rotated as usual, so as to soften a small part of the glass just in the centre. By the time this spot is soft, the air confined within the bulb has become heated, and therefore exerts a pressure outwards, which is sufficient to blow the softened part outwards and make a hole right through. The bulb is usually held in the flame and rotated by the left hand, while at the same time the right hand is heating the tip of one of the 6in. glass tubes. As soon as the hole appears in the top of the bulb the softened end of the tube is stuck over it, and the junction is held in the flame and thoroughly worked and melted together, and to assist the operation it is several times blown into and swelled out and reduced down again, finally being left contracted close to the bulb as in the case of the tube-blown bulbs. If the bulb is not required for use for some time the ends should be sealed up.

(To be continued.)

LANDMARKS IN THE HISTORY OF ELECTRO-CHEMISTRY.*

BY W. W. HALDANE GEE, B.SC., F.C.S.

In an age so essentially electrical it may be assumed that everyone is familiar with the favourite experiment of exploding mixed gases by an electric spark with the help of a contrivance known as Volta's pistol. This was a metal or strong glass vessel, sometimes a brass cannon fitted with an arrangement for passing a spark through the mixed gases with which the vessel was filled.

In April, 1781, Dr. Priestley using this apparatus and making what he terms a "random experiment" for the purpose of "entertaining a few philosophical friends," exploded air or oxygen with hydrogen in a closed glass vessel by means of the electric spark. It was observed that the sides of the glass vessel became covered with moisture, but no particular note of this circumstance was taken at the time. One of the friends who witnessed the experiment proposed to test by means of this apparatus whether "heat was heavy or not." For this purpose a copper flask was filled with air and hydrogen, weighed, and then the spark was passed. Great heat was evolved by the explosion, after the dissipation of which the flask was again weighed. After several trials it was concluded that a loss of weight occurred, and consequently that heat is a ponderable body. The experiment was repeated by that extraordinary man, Cavendish, time after time, in his laborious and accurate manner. His result was to negative the conclusion at which Priestley had arrived. In these experiments Cavendish used a strong glass vessel and confirmed Priestley's observation of the deposition of dew. This phenomenon he considered likely to throw light upon the question, at that time unanswered, as to what becomes of the oxygen which disappears during combustion. The explosion in the globe gave too small a quantity of liquid for satisfactory examination. He then used a larger volume of the mixed gas, and exploded it in a cylinder. The resulting liquid he found to be without taste or smell, and finally concluded that "this dew is plain water, and, consequently, that almost all the inflammable air and about one-fifth of the common air are turned into pure water." In the course of his experiments on the explosive combination of hydrogen and oxygen, Cavendish employed at different times apparatus of various forms. That used in the experiments mentioned above he describes as a glass globe furnished with wires for the passage of the spark, with a brass stopcock, and a means of attachment to the arm of the balance. The pear-shaped "Eudiometer" which forms the badge of the Cavendish Society (Fig. 1) is very different in construction. "Were Cavendish," says Dr. Wilson in his "Life of Cavendish," "alive among us, he would not recognise the modern instrument as resembling any part of his apparatus, and it would startle him to hear it called his Eudiometer." Yet in the cartoon of Mr. Ford Madox Brown at Owens College, Cavendish is represented as carrying an elegant pear shaped vessel. The apparatus presented to the Royal Institution by Sir Humphry Davy, and known as Cavendish's Eudiometer, has a completely different form (Fig. 2). It consists (according to Dr. Wilson—*see* "Life of Cavendish," 476) of a brass cylinder, about 6in. long and 2in. in diameter, fastened down to a piece of deal by means of two iron staples. The cylinder is closed at the extremity to the left of the figure by a plate, the centre of which is perforated for the reception of a stopcock for the purpose of connection with an air-pump to exhaust the vessel before filling it with the mixed gases. The bent piece of metal attached to the handle was probably for giving greater leverage

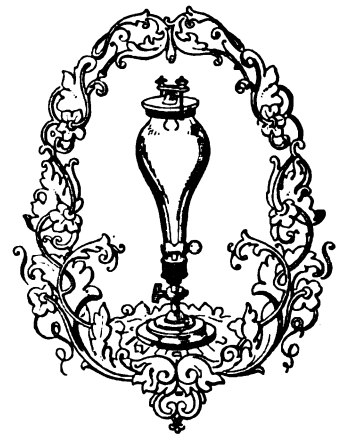

FIG. 1.—Cavendish Society's Badge.

and better control over the stopcock. There is a second stopcock furnished with a drawn out jet for the purpose of drawing off the water after the explosion. By the side of the opening for the stopcock is another aperture, into which is screwed a perforated nut containing a short piece of thermometer tube, the bore of which contains a wire passing into the cylinder. This evidently furnished the means of passing the electrical spark. The term "eudiometer" as applied to these instruments would be new to Cavendish. In his time it was restricted to the apparatus in which nitric oxide was mixed with air for the purpose of ascertaining the goodness of the air. Modern chemistry retains the eudiometer for gas analysis as a straight graduated tube with wires sealed into the glass for the purpose of passing the spark.

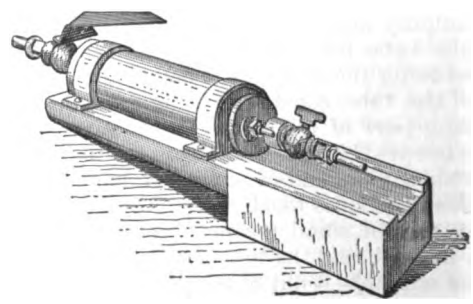

FIG. 2.—Cavendish's Eudiometer.

The liquid obtained by the spark experiments in which *air* was employed instead of pure oxygen was, however, found to be acid. Following up this observation, Cavendish made another important discovery, that of the composition of nitric acid, in which the aid of electricity was again invoked. Air was confined in a glass tube, bent at an angle which, after being filled with mercury, was inverted so that the open ends of the tube were beneath the surface of mercury in two glasses partly filled with this liquid. Air was then introduced by means of a bent tube of peculiar shape. Sparks were passed across the air. On introducing above the mercury a solution of potash a diminution of volume was noticed. More air was then introduced, the sparks again passed, and the process repeated until the liquid would absorb no longer. On evaporating the liquid to dryness, a white, solid salt-like sub-

Digitized by Google

stance remained, which Cavendish identified as nitre (potassium nitrate) by its property of forming touch-paper. By this and many auxiliary experiments Cavendish proved beyond the possibility of doubt that nitric acid is formed by combination of the nitrogen and oxygen of the air. It must be remembered that by an acid was meant, at this date, the substance we now term the anhydride, the body that is, which, on dissolving in water, forms the acid. The work of Cavendish must have been tedious in the extreme. He laboured at the frictional machine an hour a day. It is, indeed, not surprising that others failed in the experiment, and that, in consequence, doubt was thrown on the accuracy of his results. In reply to the statement of these doubts, Cavendish said that "as this experiment has been tried by some persons of distinguished ability in such pursuits without success, I have thought it right to take some measures to authenticate the truth of it." For this purpose several distinguished members of the Royal Society met together and repeated the experiment, at length, successfully. The discovery was finally established in 1788. Dr. Black, in his lectures, says of it: "This discovery of Mr. Cavendish is one of the most important in the whole history of chemistry." It was the last of Cavendish's published researches on chemistry. Thenceforth he devoted himself to the prosecution of other branches of natural science, and although he lived to see the brilliant achievements of Davy there appears to be no record of his employing the superior apparatus to be presently described.

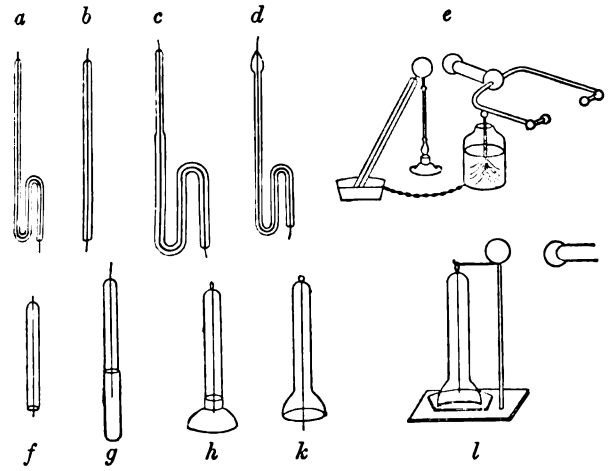

FIG. 3.—Different forms of apparatus for the decomposition of water by electricity.

The decomposition of water by electricity was first effected by Messrs. Paets van Troostwyk and Deiman, assisted by Mr. Cuthbertson. Their experiments are described in the *Journal de Physique* for 1789. Different types of apparatus employed by them are shown in Fig. 3, *a* to *e*. One form consisted of a tube 12in. long, with a bore of $\frac{1}{8}$in. in diameter, with a gold or platinum wire sealed in the top. Another wire, also of gold or platinum, was introduced into the open end of the tube, a space of about $\frac{5}{8}$in. being left between the wires. The tube was filled with distilled water, freed from air by an improved air-pump, and the open end was immersed in mercury. By means of a large electrical machine of two plates of 31in. in diameter, and a Leyden jar, electrical discharges were sent through the water, as shown by Fig. 3, *e*. Gas was liberated, and when sufficient had been collected to reach nearly the bottom of the upper wire, a discharge caused almost the whole of the gas to disappear, and water again filled the tube. The experiment was, however, a difficult one, and lacked confirmation until Dr. Pearson published his "Experiments and Observations, made with the view of ascertaining the nature of the Gas produced by passing Electric Discharges through Water," in the *Phil. Trans.* for 1797. He used an improved apparatus (*see* Fig. 3, *f* to *l*). A tube, about 4in. long and of about $\frac{1}{5}$in. bore is provided, as before, with a wire, which extends down to a brass tube, which it almost touches. Another kind of apparatus employed is also shown in Fig. 3, *h*. A glass tube, half an inch wide, has a brass funnel fixed at one end, but afterwards the tube was blown like a funnel (*see* Fig. 3, *k*), arranged in a brass dish (Fig. 3, *l*). The distance of the end of the wire from the dish was about one-twentieth of an inch. With this apparatus gas was obtained much more readily than with the original apparatus on account of the greatly lessened resistance. The experiments were, however, still very laborious, as the following extract from the description of the experiments show:—

"Experiment 1. At 0h. 40m. p.m. began to produce discharges with a double plate 24in. machine in water taken from the cistern; and at 12h. 6m. p.m. of the same day there had been written down 10,200 discharges, each of which occasioned air to ascend from the bottom of the wire and brass cup. The quantity of air obtained was now apparently about one-quarter of a cubical inch." Next day 6,636 additional discharges were passed. At this time "I was surprised on the passage of a discharge by a vivid illumination of the whole tube and a violent commotion within it, with, at the same time, the rushing up of water."

The general evidence of his experiments convinced him that oxygen and hydrogen were produced by electric discharges; and he remarks that "if experiments be proposed in which electric discharges must be passed through water or other fluids, for even a much longer time than was consumed in performing those referred to, or related in this Paper, it may be an object to employ the wind, or, perhaps, the power of a horse to turn the electrical machines, the expense of labourers being considerable."*

(*To be continued.*)

OCEAN TELEPHONY.

(COMMUNICATED.)

The question of long-distance submarine telephone cables is one which had already attracted attention, and recently, as our readers know, Prof. Silvanus Thompson read a Paper at Chicago on the subject. As it may sooner or later cause some alarm to proprietors in telegraph companies which own, to the value of 40 millions sterling, the ordinary form of submarine cable, it may be as well that the matter should be impartially considered in advance.

The idea that a merchant in London could converse direct with his correspondent in New York is no doubt a somewhat captivating one, especially as questions could be asked on both sides and explanations given to a degree not possible in practice with telegraphy. But careful reflection shows that there are even greater difficulties to the general use of suboceanic telephony than the mechanical and electrical problems which have still to be solved. To begin with, taking England, or, rather, the West of Ireland, and the United States as being the most favourably situated for the purpose, the difference in time (4 hours 56 minutes) would greatly limit the use of the telephone during business hours, because when it is 11 in the morning in New York it is 4 p.m. in London. Telegraphically considered, the concurrent working hours of the two places, therefore, do not exceed three per diem. Again, to earn a sufficient revenue on such a cable, the tariff for telephonic conversation would have to be so high as to be absolutely prohibitive. In the case of the wire between London and Paris the rate is 8s. for three minutes' talk. The fact is, as business men know by painful experience, that even between two parts of the same city there are many drawbacks to the use of the telephone. Frequently the line is engaged, the person one wishes to speak to is out or in another part of the building, the apparatus is out of order, or owing to deficient articulation, slight deafness, or cross talk, it is difficult to catch what is said. Some of these objections would apply with tenfold force to submarine telephony.

Again, it is exceedingly improbable that important transactions—and matters must be important to necessitate the use of an Atlantic cable—would be arranged by telephone, which leaves not the slightest record or evidence, and may be overheard by others. Coding in telephony is practically impossible. Next, there is no limit theoretically to the working of a submarine cable of any length, provided the amount of copper

* Wollaston, in 1801, showed that by using gold points as electrodes it was possible to decompose water by means of an ordinary frictional machine.

Digitized by Google

and gutta-percha per mile are adequately increased, but the question of expense makes a line much exceeding 2,000 miles out of the question. No doubt a similar limit as to the length at which telephone cables might be workable would be found to exist. Applying this argument to telephoning from this country to Australia or New Zealand—where it is midnight at our noon—it will be seen that the message would have to be repeated at least eight times by operators who would know nothing of the subject matter, and some of them, possibly, be unacquainted with the language in which the message was originally spoken. It would be a very curious message by the time it was delivered, since there can be no question that the ear is much more easily deceived in regard to articulate telephonic sounds than is the eye with reference to telegraphic signals, which are moreover recorded, and the message after being written can be checked by the record.

It follows, therefore, that interoceanic telephone messages would only, if at all, be practicable over distances which enable the persons concerned to talk to each other. To imagine that the possibility of talking across an ocean (when already you can communicate in writing) is likely to cause a revolution in every department of life, or to give a powerful stimulus to trade, is simply to altogether over-estimate the probabilities of the case. Even if ocean telephony is found to be feasible, the number of telegrams now sent will be very little affected; and it must, further, be remembered that, if the idea be feasible, one, two, or three telephone cables across the Atlantic would be of very little use.

From the point of view of shareholders in existing submarine telegraph companies, it may be pointed out that if it be hereafter found that sub-oceanic telephony is possible, that there is a demand for it, and that it is commercially successful, there is nothing to prevent existing companies, some of which have very large reserves, laying suitable cables as an additional string to their bow. We can all appreciate the enthusiasm and perseverance which led to the successful laying of the Atlantic cables, because there were then no means of rapid communication, and it was absolutely certain that, once established, a very large number of telegrams would be exchanged; but where is the capital likely to be found for an experimental telephone cable which would only enable one to hear his correspondent's voice instead of reading the written message?

There are many instances in which inventions, especially where there is an element of sentiment, have been elaborated after great research, labour, and expense, with the result that it was found after all no one wanted them. This is not unlikely to be the lot of those who are turning their attention to sub-oceanic telephony. The experiment would have to be on a very large scale; in the case of the Atlantic it might cost nearly half a million sterling; and if it were found impossible to use the telephone, or, if capable of being used, there were no demand for it, the cable would be, as Prof. Thompson admits, probably useless for ordinary telegraphing, although it might be available for high-speed automatic, for which, however, taking his estimated speed of 400 words per minute, it is clear there is not sufficient traffic. Taking the average number of words in practice transmitted daily over a cable as 7,000, it will be seen that the automatic at 400 words per minute could transmit this number of words in about 20 consecutive minutes *if they were all handed in for transmission at the same time.* Perhaps Prof. Thompson's idea is that if the tariff were reduced to one fourth, the volume of traffic would be increased four or five fold, but all experience is against this. Even at 3d. per word people would not telegraph to America for the pleasure of the thing, or unless they had more or less urgent occasion.

Finally, before the subject is carried any further, it would be as well to ascertain if such a cable as Prof. Thompson describes could be tested, and the faults, which would undoubtedly occur, be localised. Unless such a method be found, it would be as reasonable to talk of telephoning to Mars. Prof. Thompson says that if it is possible to increase the speed of telegraphing eight-fold, a cable to effect this will certainly be made and laid, and certainly an increase of working speed would be very desirable during the busy part of the day; but a great deal could be done in this direction by laying cables of the existing type with very large cores, which would not cost nearly so much as an experimental cable of the kind described, and would permit of a considerable increase in speed in automatic working.

At the same time, it is to be hoped that those who have taken the matter up will continue their efforts to increase the speed of working long cables. It is certainly curious, as Prof. Thompson says, that the method of working now is practically the same as it was 20 or more years ago, and the writer has sometimes thought that the eminent position held by Lord Kelvin in the electrical world, and his unsurpassed knowledge of the conditions of submarine telegraphy may, perhaps unconsciously, have deterred cable men from attacking the subject boldly. On the other hand, it will certainly be no easy task to improve upon that beautiful and sensitive instrument—the syphon recorder. To those who understand the conditions of long cable working it argues no small amount of courage on the part of Prof. Thompson, Mr. Preece, and others that they should not only bring their great abilities to bear on the problem of rapid automatic working on long submarine lines by a new type of cable, but should endeavour to render possible sub-oceanic telephony.

A NEW INCANDESCENT ARC LIGHT.*

BY L. B. MARKS.

Electrical literature is replete with studies of the incandescent lamp as a source of artificial illumination; the performances of arc lights under a great variety of conditions have also been published from time to time. But the subject of the so-called incandescent arc, singularly, has received little or no attention. In view of this fact it has seemed desirable to report at once, on a series of investigations, which, though still incomplete, have disclosed some remarkably interesting and important phenomena with reference to a new form of incandescent arc light. The experiments have been carried on far enough to demonstrate that this source of illumination is *sui generis*. While possessing the main characteristics of the ordinary arc, it is also akin to the incandescent light, and may be said to constitute a mean between these two.

The incandescent arc has been described as one in which the "two electrodes are in imperfect contact," the current thereby meeting with a high resistance and producing heat effects, which manifest themselves in the incandescence of one electrode and the formation of a number of very small arcs between the uneven parts of the electrodes in contact.† On this principle, Reynier, Werdermann, Joel, Tommasi, and others, constructed lamps years ago, but for well-known reasons none of these "semi-incandescent" lamps, as they were called, found much practical application. The Sun lamp of Clerc and Bureau was a modification of the others, the arc impinging on the surface of a block of marble or condensed magnesia between the tips of the electrodes. In this form there was a rapid waste of the non-conducting substance interposed, and a diminution in the efficiency of the light.

The *incandescent arc* to be treated of in this Paper differs radically from any of the forms alluded to above. In it the electrodes are not in contact, while the current is indirectly used in maintaining all the products of disintegration of the carbon in a state of incandescence or opalescence.

Plate A shows the main features of the appurtenance. It will be seen that the arc is enclosed in a small envelope, which is made of highly refractory glass. The envelope is closed at the bottom and provided on top with a metal plug having an opening in it just large enough to admit of the feed of the upper electrode. A fireproof plug of asbestos-pulp insulates the metal from the glass. A valve, shown in the plate, allows the egress of gas, but prevents ingress of the air. With this construction the operation of the lamp will be as follows:—Upon the closure of the circuit, and the springing of the arc, the air in the enclosing envelope is robbed of its oxygen, the latter uniting with the carbon of the electrodes to form CO and CO_2 gases. The gases are brought to an exceedingly high temperature at which they maintain the carbon vapour issuing from the arc. This vapour is deposited in the form of a thin coating on the internal surface of the glass chamber. The expansive force of the gases may become sufficiently great, if no means of egress be provided, to rupture the envelope; hence, a small safety-valve is provided for their outflow. The only possibility of ingress of air is through the narrow space between the positive carbon

* Paper read at the International Electrical Congress, Chicago, August, 1893.

† Julius Maier: "Arc and Glow Lamps," p. 263.

Digitized by Google

and the plug. Experience has shown that after the temperature has been raised beyond a certain point the amount of air that enters in this way is inappreciable ; in any event, the oxygen is immediately converted by combination.

It is important that the enclosing glass envelope be as small as possible, for the conservation of the radiant energy, and hence the efficiency will depend largely upon the size of the chamber. The heat which, in the ordinary arc light is dissipated in the air, is here conserved, and raises the temperature of the enclosed gases and vapour of carbon. The proper conditions being fulfilled, the lamp maintains its maximum efficiency shortly after the current has been passed through it, and glows like the incandescent with the brilliancy of the arc light. The arc proper is scarcely visible, but the entire contents of the chamber seem to be luminous, giving the appearance of a solid cylinder of light.

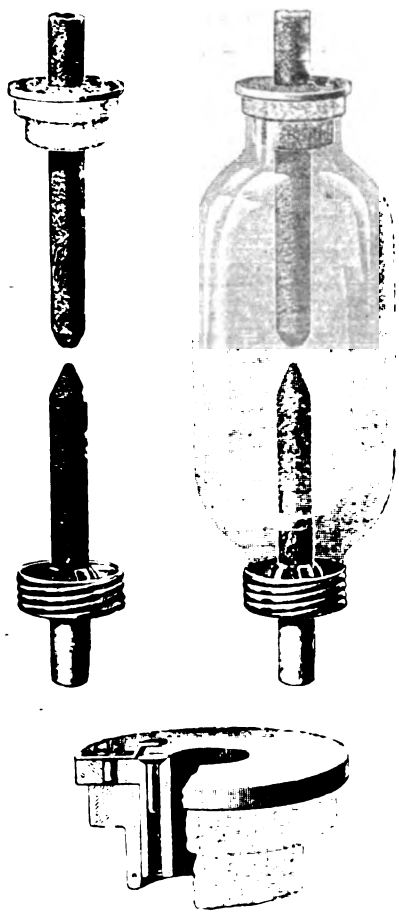

PLATE A.

The pressure, as well as the temperature of the enclosed gases, has a very important bearing on the performance of the lamp, and affects to a marked degree the character of the carbon deposit on the glass chamber. At this date no definite figures can be given, but it appears that a high tension is absolutely required to give good results. The structure and constituency of the electrode are also pre-eminently important. Absolute purity of the carbons is imperative.

Investigators in this field have apparently found it impossible to obtain all the requisite conditions. Beardslee* mentions a type of lamp similar to the one under discussion, but whether the size or character of the arc-enclosing chamber, the nature or management of the gases, or the quality of the electrodes, or other features made his arrangement impracticable, is not recorded. Suffice it to say, the comparatively poor grade of arc light carbon manufactured ten years ago would alone explain his failure.

It is interesting to note here that attempts have been made at various times to save carbons in arcs by excluding the oxygen of the air. Baxter† devised several forms of arc lamp with this object in view. The subject has been more recently referred to by Thomson‡. These experiments were attended with little practical success ; not because the desired ends were infeasible, but probably because, as in the case of Beardslee's apparatus, alluded to above, one or more of the requisite conditions had not been attained. It appears that the saving in life was more than counterbalanced by the loss in light. The "incandescent effect" was absent, and the unsteadiness of the arc itself was fatal. The results were almost identical with those obtained when the arc is formed *in vacuo*. In this case there is a tendency of the carbon to deposit as a soot on the sides of the vacuum chamber, an effect consequent upon the vaporised carbon in the arc being carried off and condensed again, as soon as the vapour escapes the heat of the arc stream. But the requisite conditions hereinbefore named being once attained, the arc is really a beautiful phenomenon. It differs in many respects from the arc in open air, being especially steadier than the latter. The light, emanating from the incandescent vapour of carbon, appears to issue from all parts of the small enclosing envelope, the area of the source of illumination being limited only by the size of the chamber.

Measurements of the efficiency and candle-power of the light were made in the laboratory of Cornell University. The method employed in making the efficiency tests was that used by Nakano* in determining the efficiency of the arc lamp, and subsequently by the writer in an investigation on arc light carbons.† The ratio of luminous to total radiation of the lamp was taken at different angles below and above the horizontal. The values obtained are given in Table I, where L equals luminous radiation, T equals total radiation, and $\frac{L}{T}$ equals radiant efficiency. Fig. 1 represents the curves plotted from these values, the dotted line curves showing the distribution of luminous and total radiation respectively, and the full line curve the measure of the efficiency below the horizontal. The value of the mean hemispherical efficiency is obtained by integrating the curve, and is found to be 8·4 per cent. The mean efficiency of the ordinary arc is about 10 per cent.‡ The

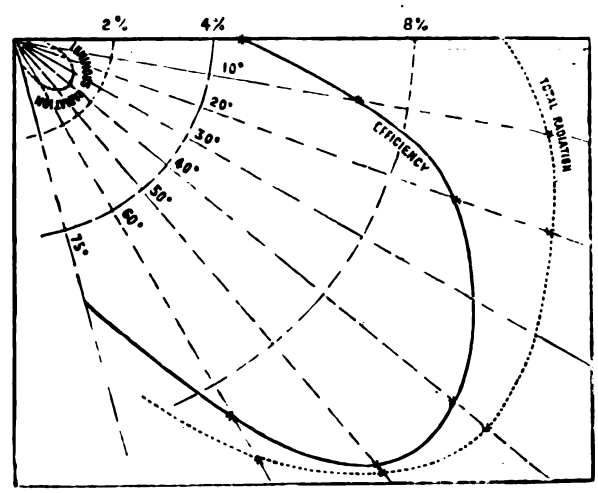

FIG. 1.

mean efficiency of the incandescent lamp, according to Merritt,§ is rather below than above 5 per cent. The value obtained in the test of this new light therefore lies between those of the two present forms of electrical illumination, approaching, however, more nearly that of the arc. While it is true that the average efficiency of the electric arc in open air nets is about 10 per cent., it is questionable whether in commercial practice in this country this value is often reached. The writer has made tests of a standard brand of arc-light carbon where the efficiency was only $7\frac{3}{4}$ per cent.||

Glancing at Fig. 1, we note that while the form of the efficiency curve differs entirely from that of the incandescent lamp, it is not unlike that of the arc. The distribution of light-giving energy is, however, more uniform than in the arc, a fact which is more prominently brought out in comparing the candle-power curves of the two. While the approximate law, *hemispherical efficiency*, $= 1/4$ *horizontal*, $+ 3/4$ *maximum*, holds for the ordinary arc, the mean of several tests indicates that *hemispherical efficiency* $= 1/2$ *horizontal* $+ 1/2$ *maximum*, fairly represents the conditions manifested by the

incandescent arc, curves, Figs. 1 and 2. Tests were made to determine the effect of initially coating the surface of the cylinder with various ingredients other than carbon. No marked difference in the efficiency was discovered. Fig. 2, plotted from values in Table II., represents a curve taken in this way. The mean hemispherical efficiency was 8·02 per cent.

TABLE I.—*Efficiency Measurements.*

TABLE III.—*Candle-Power Measurements.*

Mean current = 8 amperes. Mean potential difference = 63 volts.

Angle.....	0°	-10°	-20°	-30°	-40°	-50°	-60°	+20°
Candle-power...	218	283	455	590	595	515	450	170

Table III. gives the candle-power measurements from which the curve (Fig. 3) was plotted. Distances measured along the radii give the candle-powers for the various angles throughout the "zone of useful illumination." It will be seen that the distribution of light, as shown by the candle-power curve, differs considerably from that of the ordinary arc. Especially is this true at angles greater than 50deg. below the horizontal. The turn in the curve is not so sharp as in the arc, and there is much less difference between the maximum and the mean amount of light; in fact, to the naked eye the intensity of luminous radiation does not seem to vary much from 20deg. to 60deg. below the horizontal, while in the arc the change is very marked between these limits. Thus the formula of Gérard‡, namely, *hemispherical c.p.* = 1/2 *horizontal c.p.* + 1/4 *maximum c.p.*, which may be used to advantage in arc light approximations, will not hold in this case; but the form of the curve, as well as the nature of efficiency curves above referred to, suggests the substitute—*hemispherical c.p.* = 1/2 *horizontal c.p.* + 1/2 *maximum c.p.* The mean or hemispherical candle-power below the horizontal, obtained by integration of curve Fig. 3, equals 431, thus allowing 1/17 watts per candle, or 637/6 candles per electrical horse-power—nearly three times the average illumination of the incandescent lamp using the same energy. The results of tests show that the mean hemispherical candle-power of the ordinary arc, measured as in the above case, averages about 600; the mean watts per candle, 0·84 or 888 candles per electrical horse-power.

Comparing these measurements with those of radiant efficiency, it appears that the ratio *hemispherical c.p.*, "*incandescent-arc*"/hemispherical c.p. ordinary arc is considerably smaller than the ratio *hemispherical efficiency*, "*incandescent-arc*" hemispherical efficiency, ordinary arc.

The explanation of this difference undoubtedly lies in the quality of *luminosity* of the light omitted by the *incandescent arc*. Nichols‡ has pointed out that the relative efficiency, as determined by the ratio *luminous radiation*/total radiation, "does not coincide with that obtained from the ratio of candle-power to watts, for the reason that the various rays which make up the visible spectrum do not enter into the production of candle-power in proportion to their energy." Luminosity is a potent factor in determining the real efficiency of any source of illumination. Lack of time has prevented the investigation of this important phenomenon, but, at its maximum efficiency the light from this form of *incandescent-arc*, though not so intense, unmistakably appears brighter than that of an ordinary arc of equal candle-power as interpreted by the photometer.

‡ M. Gérard: "Candle-Power of Arc Lamps." *Centralblatt für Elektrotechnic*, January, 1890.

‡ Dr. Edward L. Nichols: "The Efficiency of Methods of Artificial Illumination." *Trans.* Amer. Inst. Elec. Eng., Vol. VI., No. 5, May, 1889. See also *The Electrician*, Vol. XXII., p. 601.

Oxygen being practically excluded from the arc enclosing chamber, prolongation in the life of the electrodes is an implied concomitant. In the ordinary arc "while the positive carbon loses by volatilisation from its tip or crater, and by combustion from its sides, the negative gains no deposit, but wastes at a less rate than the other, and by *combustion only*."‡ Hence, if the exclusion of oxygen were complete, we might expect an indestructible negative. This condition, however, has not been fulfilled in any of the tests made thus far, but the results fully substantiate the theory. Absence of combustion on the one hand, and the tension of the enclosed gases on the other, combine to greatly reduce the amount of disintegration of the positive electrode.

Table IV. gives the results of life test with a pair of pure carbons, 1/2 in. diameter, and specially constructed for the purpose. The lamp was placed in the circuit of a constant current dynamo, running about eight hours per day; readings were taken at given intervals, and the total length of run was limited to 100 hours.

TABLE IV.—*Life Tests.*—1/2 in. carbons.

Mean current = 9 9/16 amperes. Mean potential difference = 55 volts.

Initial length (+) carbon (in.).	Initial length (−) carbon (in.).	Duration of run (hours.).	Loss in length (+) carbon (in.).	Loss in length (−) carbon (in.).	Life per inch (+) carbon (hours).	Life per inch (−) carbon (hours.).
10·31	4·63	100·0	6·81	0·69	14·67	145·45

Thus making 1·69in. per hour as the average consumption of carbon in the commercial 350 watt-lamp, run at 5 1/2 amperes and 50 volts,† we note that although 525 watts, or one and one-half times the energy have been expended in the case of the lamp under consideration, yet the life per inch of carbon consumed is more than *twenty times* that of the other. Indeed the figures show that the life of the negative was nearly *one hundred times* as great as that obtained in commercial practice to-day.

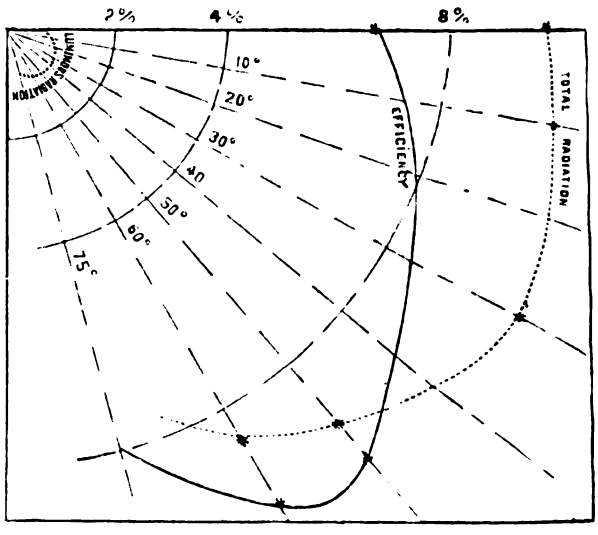

FIG. 2.

The preservation of the negative is a very interesting feature of this type of lamp. There is a marked tendency towards deposition of the products of volatilisation of the upper electrode, on tip of the lower, the carbon deposited, if not ruptured by the action of the lamp, forming an integral part of the negative. In one case, where the arc having been sprung the electrodes did not come in contact during the entire run, this "building up" process was beautifully exhibited, the negative electrode gaining practically all that the positive lost. The current in this instance was 10 1/2 amperes, and the potential difference 50 volts. The duration of the run was 11 hours.

The effect of the enclosed gases on the form and character of the arc presents a large field for investigation. On account of lack of sufficient data no attempt will now be made to state much of a definite nature regarding this subject; but it is hoped that the matter will be given due attention in the near future. The difference in potential between the electrodes being equal, the *incandescent arc* is longer for a given current than the ordinary arc

Under some conditions it has been found to be almost twice as long. If we accept the conclusion of S. P. Thompson, that "the arc is independent of the nature of the surrounding gas,"* we must then look to the effects of the tension or pressure of the heated gases upon the arc to explain this difference in length. It has been found that there is a constant increase of potential difference with pressure above atmosphere for a given current and length of arc.† But in spite of this fact the decrease in resistance of the arc under the conditions named appears to allow of a greater length for the same potential difference.

In the ordinary arc the carbon vapour carried off from the positive is consumed by the oxygen of the air before it can deposit on the negative. Hence the ever present "zone of flame," as distinguished from the arc flux proper, is really a zone of combustion. In the *incandescent arc*, however, there is naturally no zone of flame, consequently the phenomenon of *flaming* common to the ordinary arc does not occur. The arc tends to centre itself, being probably aided in so doing by the pressure of the surrounding gases; moreover, the slow consumption of the electrodes lessens the tendency to wander. With cored carbons there is a perceptible crater, but with solid pencils the tips become more or less flattened.

The quality of the carbon has an important bearing on the potential difference between the electrodes. Generally speaking, it has been observed that with soft fine-grained carbons the potential difference is considerably lower for a given current than with harder or coarse-grained pencils. The tendency to *hiss*, however, is not so marked when the electrodes are consumed in the gas chamber as in the open air; in the former case the disintegration is so slow that the "electrolytic" vaporisation, as it has been called,

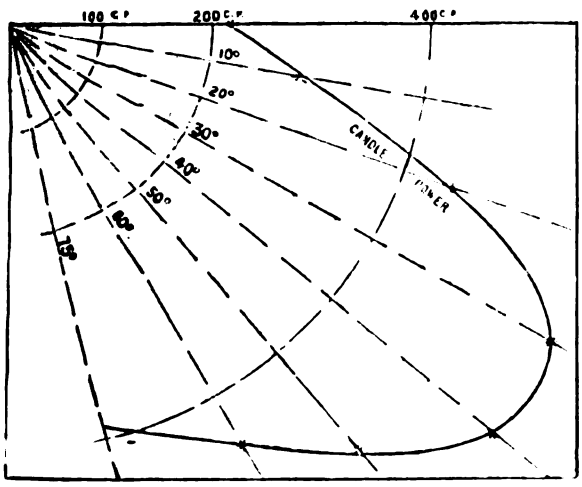

FIG. 3.

does not appear to explode the particle. It is interesting to note here that these results confirm a theory of *hissing* advanced by Prof. Thomson a few years ago.‡

No measurements were made using the alternating current, but the appurtenance was applied to the alternating-current arc lamp to determine the effect on the noise of the arc. The *hum* was in a large measure reduced, but whether the reduction was due mainly to the mere fact of the arc being enclosed in an air-tight compartment or not is questionable. But as the *hum* became much slighter after the lamp had been in operation several minutes, the action of the heated gases being then manifest, it is plausible that the diminution in the noise was not due entirely to the shielding property of the glass envelope. While it has been proven that "the humming of the alternating-current arc is due to the rapid periodic extinction and re-establishment of the discharge,"§ the singing tone may be greatly modified, if not entirely overcome, by the substitution of any incandescent arc of the Reynier type. A few years ago the writer had occasion to test an alternating current arc-lamp trimmed with carbons which had been provided with a core of pulverised mica and carbon. The springing of the arc was accompanied by the usual *hum*, but as soon as the mica fused the noised ceased. The conditions were similar to those of an *incandescent arc*, the plastic mica-carbon core constituting a high-resistance medium between the plus and minus electrodes. There was really no true arc. The amount of light was naturally greatly reduced. In the case of the *incandescent arc* first alluded to, there seems to be an approach to these conditions, the arc-stream acted upon by the gases enclosed in the chamber appearing to have a greater density, if we may call it that, than under normal circumstances. The amount of light in this experiment was, however, apparently as great as in the direct-current tests.

Unquestionably this form of *incandescent arc* must have a wide application to the arts. As a substitute for the ordinary arc light, where greater steadiness or longer life is required, its superiority will be manifest. And its utilisation, where at present the incandescent lamp is the only satisfactory source of illumination, also presents a large field. The effective distribution of luminous energy, and the colour of the light, make it for many purposes a desirable mean between the incandescent and the arc. As a standard source of illumination for arc-light comparison and measurements, it may be of much scientific, as well as utilitarian, importance.

The investigations have been carried out under the direction of Mr. Louis E. Howard, and many of the facts herein stated are due to him. The writer is also indebted to Dr. Edw. L. Nichols, Franklin L. Pope, and Robert H. Read for valuable suggestions; to Mr. C. Ransom for life tests, and to Messrs. Wm. C. Hubbard and E. S. Ferry for assistance in the efficiency and candle-power measurements.

THE PRACTICAL MEASUREMENT OF ALTERNATING ELECTRIC CURRENTS.

BY PROF. J. A. FLEMING, F.R.S.*

(*Continued from page 478.*)

III.—*The Measurement of Alternating-Current Power.*

Having dealt in the preceding lectures with the subject of the measurement of alternating-current strength and alternating-current pressure, I propose to consider now the measurement of alternating-current power. When the current is flowing through a conductor it dissipates energy, and the rate at which this energy is dissipated is spoken of as the *power* taken up in that circuit. When a constant current is flowing through a conductor, if we measure the current in amperes and the difference of potential in volts, then the product of these two numbers gives us the power taken up in the circuit measured in watts. In this case two simple measurements give the required rate of dissipation of energy in the conductor. If, however, we have to deal with an alternating current, in which the current strength is varying from instant to instant, according to a periodic law, and if, likewise, the difference of potential between the ends of the circuit is varying in the same periodic manner, we cannot always obtain the measurement of the mean power taken up in the circuit, generally speaking, by taking the product of the $\surd$/mean-square amperes and $\surd$/mean-square volts. What we really require in this case is the mean value of the power taken up in the circuit. We can obtain the measurement of the mean power if we can measure at every instant the true value of the current strength and the difference of potential, supposing these instantaneous values of the current and pressure known at equidistant intervals taken throughout one complete period; if we then multiply the instantaneous value of the current by the corresponding value of the pressure, or difference of potential, and multiply these together, we obtain a number representing the instantaneous value of the power, and if we imagine the period divided into a large number of equidistant intervals of time, and those products taken at every such instant, then the mean value of these products, taken throughout the period, would give us a close approximation to the mean value of the power being absorbed by that circuit.

We have seen in a previous lecture how it is possible to determine and describe curves representing the instantaneous values of the current and E.M.F. in the case of an alternating-current circuit; but this in general is not a simple matter to do, and we have therefore to resort to other methods of obtaining the required result. In dealing with the power taken up in alternating-current circuits, there are two cases to be considered. The first case is that in which the circuit is non-inductive. In that case, as before explained, the impedance of the circuit is the same as its resistance, numerically speaking. For such circuits the alternating current flowing in the circuit is in step, as regards phase, with the alternating potential difference between its extremities. When this is the case the power taken up in that circuit can very easily

* Abstract of Cantor Lecture delivered before the Society of Arts, February, 1893.

Digitized by Google

be measured. If we measure the √mean-square value of the alternating current by means of any of the balances of dynamometers, described in the first lecture, and if, by means of any of the electrostatic or thermal voltmeters, we measure the √mean-square difference of potential between the ends of the circuit, and multiply these two mean-square values together, we obtain the mean value of the power taken up in the circuit, and we arrive at the same result as if we had been able to measure separately the instantaneous values of the current and potential difference at numerous equidistant intervals throughout the phase, and taken the mean value of their products. As an instance of this, it may be pointed out that an incandescent lamp may be treated as a practical non-inductive circuit. If an incandescent lamp is traversed by an alternating current, and we measure the current flowing through the lamp by means of, say, a Siemens dynamometer, the potential difference between the terminals of the lamp by means of, say, a Cardew voltmeter, and if we multiply the two scale readings of these instruments together, we obtain the mean value of the power measured in watts, taken up in the lamp. So far, then, all is quite simple, and in dealing with any circuit which we know or can prove to be practically non-inductive, we have no difficulty, by means of two instruments of the proper kind, in determining the real mean-power taken up in the circuit. Our difficulties come in when we have to deal with circuits such as transformers, which, when not fully loaded, we know to be inductive. If, in this case, we can determine the instantaneous values of the current and difference of potential between the ends of the circuit, then, proceeding as above described, we can determine the mean value of the power taken up in the circuit. If, however, it is not convenient to do this, we cannot proceed to measure the √mean-square values of

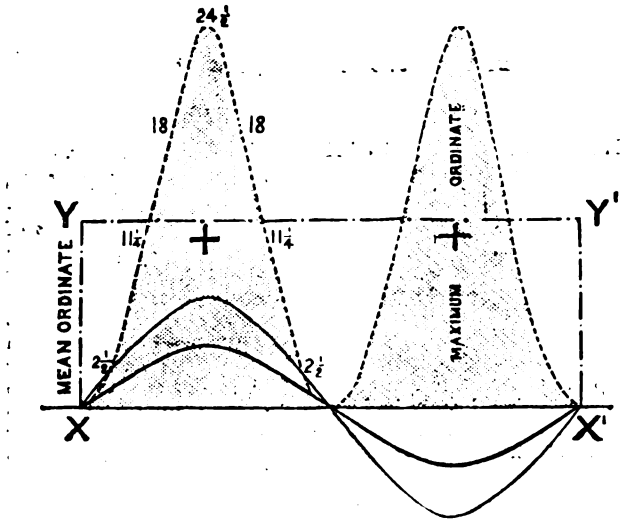

FIG. 10.

the current and E.M.F., and then multiply them together. Such a proceeding would lead to a considerable overestimate of the real power taken up in the circuit. Without going into elaborate proof of this, it may be simply sufficient to present the following figures :—

In Fig. 10 are shown two simple harmonic curves in step with one another. The semi-period is divided into equidistant parts, and ordinates are erected at each point. By squaring each of the values of the ordinates, and taking the square root of the mean of the squares, we obtain for each curve a number which would represent the instrumental value obtained by an alternating-current dynamometer or voltmeter. If we multiply together the simultaneous values of current and E.M.F., we obtain a number which represents the instantaneous value of the power taken up in the circuit, and if we take the mean value of all these separate instantaneous values of the power, we obtain the same number as we do if we take the products of the square roots of the mean of the squares of the instantaneous values of the current and E.M.F. Hence, we see that when the two simple harmonic curves are in step with one another, the product of the square root of the mean of the squares of the separate ordinates is equal to the mean value of the products of the corresponding ordinates.

In Fig. 11 are shown two periodic curves, which may be taken to represent a current and an E.M.F. curve, but one of which is displaced backwards relatively to the other. This is what happens in an inductive circuit, where the periodic current always lags in phase behind the periodic E.M.F. If we perform the same operations on the ordinates of these curves, we find that a product of the mean square values is in excess of the mean of the products. In other words, if in such circuit we measure the current by means of a dynamometer, and the potential difference between the ends by means of an alternating-current voltmeter, the product of these two numbers gives us a number which is in excess of the true value of the mean power taken up in the circuit. It is convenient to call the product of the √mean-square amperes and the √mean-square volts the *apparent watts* taken up by the circuit, and to call the true mean value of the power the *true watts* taken up by the circuit. The ratio between the true watts and the apparent watts is called the *power-factor* of the circuit. Thus, for instance, in the case of a transformer on open circuit, the transformer being of the closed-magnetic circuit type, the power factor is about 0·7 ; in other words, the real power is only ⅞ of the apparent power. In the case of a transformer of the open magnetic-circuit type, the power-factor may be as small as 0·1. Hence you see that an enormous error in this case would be committed by taking the product of the instrumental readings as simply representing the true mean power taken up in the circuit. We have, then, to consider in what way this true mean power can be practically measured in the case of alternating current circuits.

There are many methods by which this may be done. A large number of methods have been described which look very excellent on paper, but which do not in practice turn out so well. As I desire only to bring under your notice those methods which are capable of being practically employed, I shall pass over the theoretical methods, and turn at once to the description of those instruments which will enable us to measure practically the power taken up in inductive circuits. The most practical, and by far the best instrument to use for this purpose is the electro-dynamometer instrument. Consider a dynamometer, such as one of the Siemens dynamometers described in my first lecture. Let the fixed coil of this dynamometer be placed in series with the circuit in which we desire to measure the power being taken up. Let the movable cir-

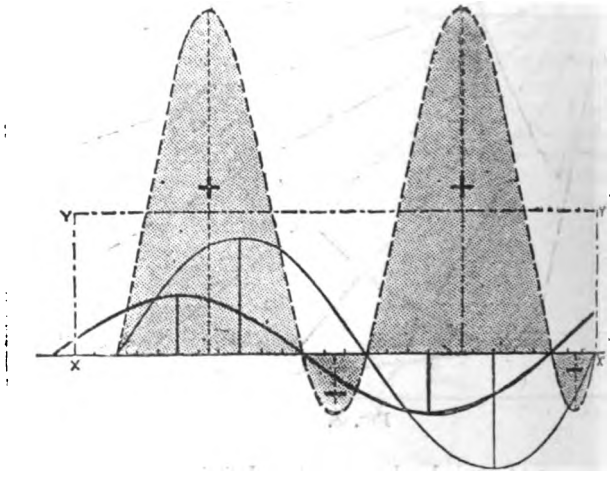

FIG. 11.

cuit of the dynamometer consist only of a few turns of wire, and let this movable circuit have joined in series with it a non-inductive resistance, which may be formed either of coils or wire, or incandescent lamps. Let this movable circuit with its added resistance be placed as a shunt across the ends of the circuit in which it is required to measure the power, being joined up, as shown in Fig. 12. Then when the alternating E.M.F. is applied to the circuit, the fixed coil of the dynamometer (now called a wattmeter) will be traversed by a periodic current identical with that passing through the inductive resistance. The movable coil of the wattmeter will be traversed by a current which will be in step as regards phase with the potential difference between the ends of the inductive circuit. When the dynamometer thus has its two circuits traversed by two currents, the force required to hold the movable circuit in its normal position against the electro-dynamic forces, is at any instant proportional to the product of these currents. If, then, the currents vary from instant to instant, and if the time of vibration of the movable coil is very long compared with the periodic time of the current, the mean value of the force required to hold the movable coil in its normal position with its axis at right angles to that of the fixed coil, will be proportional to the mean value of the product of the currents in the fixed and movable coils respectively, that is to say, will be proportional to the mean power being taken up in the inductive circuit. The force required to hold the movable coil in its normal position may be furnished by the torsion of a spring, and hence we can with such an instrument read off the mean-power being taken up in the inductive circuit, provided that the wattmeter is already standardised. The best way to standardise the wattmeter is to apply the wattmeter to measure the power taken up in a known standard non-inductive circuit, and, at the same

Digitized by Google

time, to measure the mean-square value of the current flowing through this circuit and √mean-square value of the potential difference between its ends. In this way we apply the wattmeter to measure the known power being taken up in a non-inductive circuit, and we then obtain the constant of the instrument. The conditions of success in the use of this wattmeter are as follows:—

The current through the series coil of the instrument must have the same value as the current through the circuit to be measured, and the current through the shunt coil of the wattmeter must be exactly in step with the difference of potential between the ends of that shunt circuit; in other words, the shunt circuit must be strictly non-inductive. This can only be secured by winding the movable coil of the wattmeter with no very great number of turns.

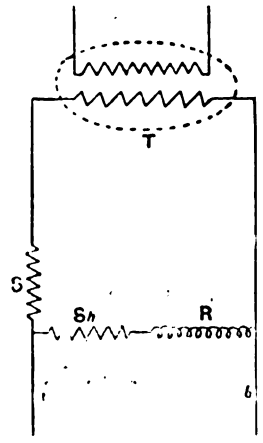

Fig. 12.

On the other hand, we then have to face another difficulty when we employ such a wattmeter to measure the power taken up in the primary circuit of transformers at high pressure. In this case, in order to obtain the sufficient magnetic moment in the movable circuit of the wattmeter, we are obliged to pass a relatively large current through the shunt circuit, and then we find that we are wasting a large amount of power in this shunt circuit. Unless this power is at disposal, it may prevent us from practically employing this method. But, fortunately, there exists another method of dealing with the matter.

In my first lecture I pointed out to you that when a transformer is being worked on open secondary circuit, or is very lightly loaded, the potential difference between the ends of the primary

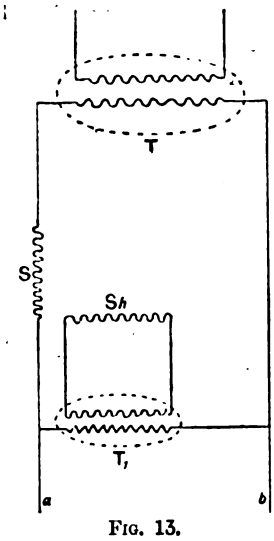

Fig. 13.

circuit is exactly opposite in phase to the secondary circuit of the transformer, of which the primary circuit is connected to the extremities of the circuit in which the power to be measured is taken up (*see* Fig. 13). We shall still have an arrangement in which the current in the shunt circuit of the wattmeter can be made to be in step with the potential difference between the ends of the inductive circuit, all other arrangements remaining the same, but in which the total power taken up in the wattmeter is very much less than in the former case.

To show the difference between these two methods, let us suppose that in the first place the wattmeter had a shunt resistance which could carry suitably one ampere, and that it is required to use the wattmeter to measure the power taken up in the primary circuit of the transformer at a pressure of 2,000 volts. We should then have to provide a non-inductive resistance capable of carrying 1 ampere at 2,000 volts, or nearly 2,000 watts expended on it. Under these circumstances, the power wasted in the shunt circuit of a wattmeter would be nearly 3 H.P. If, however, we do away with the non-inductive shunt resistance, and take a 1 H.P. transformer capable of transforming down from 2,000 to 100 volts, and put the shunt coil and the wattmeter together with a small additional resistance across the secondary terminals of this transformer, so arranging the resistance that still one ampere flows through the shunt circuit of the wattmeter, we then have the following power absorptions:—

The wattmeter shunt circuit will absorb 100 watts, and the transformer can be made to take as little as 60 or 70 watts, hence the whole arrangement, transformer, wattmeter, and additional resistance only takes up 150 watts instead of 2,000; in other words, a saving of 92½ per cent. It is clear, therefore, that the combination of the wattmeter with the transformer in this fashion is more economical than the use of a non-inductive external resistance. Generally, we may then say, that for the purpose of measuring alternating-current power, the best instrument to employ is the dynamometer wattmeter; using either one of the Siemens' form, in which the torsion of a spring is employed, or a balance form similar in construction to the ampere balance of Lord Kelvin. In those cases in which the potential differences between the ends of the circuit in which we wish to measure the power absorption does not exceed 100 volts the whole, the necessary resistances can be placed in the movable coil itself, winding it at a high resistance, so that we have as few turns as possible in that coil and yet obtain the necessary magnetic moment. We can then apply the wattmeter, standardised as above described, to measure the power taken up in any circuit inductive or non-inductive.

When we have to measure the power taken up by any inductive circuits, particularly when we are employing high pressures, as in measuring the power absorption in the primary circuit and transformers, the best method to adopt is to use a transformer in connection with the dynamometer wattmeter, as above described. The lecturer then proceeded to describe the engine-room wattmeter invented by Lord Kelvin, an illustrated description of which will be found in *The Electrician*, Vol. XXXI., p. 477.

(To be continued.)

CORRESPONDENCE.

OCEAN TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have read with much interest the report in *The Electrician* of Prof. Silvanus Thompson's lecture, entitled "Ocean Telephony," delivered before the Electrical Congress at Chicago.

The solution he offers of the problem of fast speed ocean telegraphy and telephony, and the suggestions he makes on the subject, are of special interest to cable engineers, and will no doubt direct their attention to methods by which the ideas of the professor may be submitted to practical test.

I would remark, however, that cable engineers have not been quite so indifferent to the subject as he supposes, and that some of them have given to it their serious attention for some time past.

One attractive feature of the proposed methods is that they can be carried out experimentally upon an "artificial line." Indeed, long before the Chicago lecture, I worked in almost exactly the same direction with a line equal to 1,000 miles of Atlantic cable, say, of 330 microfarads and 4,000 ohms. It is true that this apparatus possessed but a single conductor; but for many experiments this difference is not material.

The results obtained by the use of inductive shunts, placed either at the end or distributed at various parts of the line, showed so little advantage over old methods that neither was a patent applied for nor were the details of the experiments published.

One particular arrangement, represented by Fig. 7 (*The Electrician*, September 1st, page 473), was tried, using a transformer specially constructed and wound for the purpose. The results obtained with the syphon recorder were not unsatisfac-

Digitized by Google

tory, but, as will be readily understood, successive impulses of one current followed by a reversal introduced troubles in the signals. These, unfortunately, were not overcome.

Of course, this special difficulty would not arise in telephony, where every current is followed by a reversal, but it is a very real one when the instruments and alphabet used in submarine telegraphy are employed.

There can be no doubt that Mr. Oliver Heaviside, F.R.S., may be regarded as the pioneer of the work in the direction of reducing the retardation caused in cables by electrostatic capacity by the employment in the circuit of electromagnetic induction.

As Prof. Perry says, in effect, when we can understand Mr. Heaviside we know he is right, but on one point of vital importance in submarine telegraphy he seems to hold opposite views to Prof. Thompson.

The latter, speaking of telephonic signals, says: "Never for such a purpose must a cable be constructed, as Atlantic cables have hitherto been, of a single conductor (of stranded copper), surrounded by an iron sheathing that comes in between the outgoing and the returning parts of the circuit, thus adding an enormous impedance." On the other hand, Mr. Heaviside says: "It seems very probable that the iron sheathing of a submarine cable may be beneficial, although it is not easy to precisely state its full effect." "Electrical Papers on the Self-Induction of Wires," Part. VIII.

Cannot Mr. Heaviside be persuaded to give his views on the methods proposed by Prof. Thompson? It is certain that the whole of the telegraph world would receive them with the greatest interest.—Yours, &c., ARTHUR DEARLOVE.

4, Great Winchester-street.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

The 1893 Edition of "THE ELECTRICIAN" Electrical Trades' Directory and Handbook is NOW READY. This useful book contains over 1,000 pages, and several new and handy features have been added. Price 7s. 6d., post free 8s. 3d.; abroad 8s. 10d. *Comparison with any similar electrical publication is specially invited.*

TENDERS INVITED.—The Secretary of State for Foreign Affairs has learned from Her Majesty's Minister in Chili that the Municipality of Santiago have expressed a wish to receive tenders for the lighting of that city by electricity. Such particulars as are in the possession of Her Majesty's Government may be seen on personal application at the Commercial Department of the Foreign Office, between the hours of eleven and six daily.

———The Vestry of St. Pancras invite tenders for the extension of the buildings at their electric lighting station in Longford-street, N.W. Drawings can be seen at the offices of Prof. H. Robinson, C.E., 13, Victoria-street, S.W., from whom further particulars can be obtained. Tenders must sent in to Mr. T. Eccleston Gibb, vestry clerk, at the Vestry Hall, Pancras-road, N.W., by twelve o'clock noon on Thursday, the 21st inst. Further particulars are given in our advertisement columns.

TENDERS ACCEPTED.—The Electric Lighting Committee of the Lancaster Corporation have accepted the tender of Messrs. Manlove, Alliott and Co. for the supply and erection of wrought-iron roofs for the engine and boiler house; and that of Mr. C. Dennis, of Bury, for the erection of a brick chimney, at the Electricity Works, Marton-street.

APPOINTMENTS.—Mr. Frederick Siemens, of 10, Queen Anne's-gate, Westminster, announces that he has appointed Mr. Emil Biedermann and Mr. Ernest William Harvey to succeed the late Mr. John Head as managers of his civil engineering business for this country, France, Belgium, Spain, Portugal, and America. These gentlemen have for many years been engaged as engineers on Mr. Siemens' technical staff.

SALES BY AUCTION.—Messrs. Furber, Price and Furber will hold a peremptory sale under a Judge's order, of the plant, machinery and instruments of the London College of Electr cal Engineering on the premises, 9 and 10, Railway-approach, and 3, 5 and 7, Denman-street, London Bridge, S.E., on Tuesday, the 19th instant, and following day, at 12 for 1 o'clock. The plant includes a considerable variety of machinery, lathes, tools, engines, &c., particulars of which will be found in our advertising columns.———Our readers are reminded that the sale by auction by Messrs. Wheatley Kirk, Price and Goulty, of the valuable and modern plant, machinery, &c., *in re* Blakey, Emmott and Co., takes place place at the Northern Telegraph Works, Square-road, Halifax, Yorkshire, on Tuesday, Wednesday, Thursday, and Friday next.

LIQUIDATIONS.—The shareholders of the Trent Gas Engine Company (Limited), of New Basford, resolved, at a meeting held on the 23rd ult., to wind up the Company voluntarily, and Mr. Robert Mellors, accountant, of Nottingham, was appointed liquidator.

——— By resolution passed on August 10th, and confirmed on August 31st, the shareholders of the United Telephone Company of Rosario (Limited) have decided to wind up the Company voluntarily, and Mr. T. S. Hamilton, the secretary, has been appointed liquidator.

BANKRUPTCY.—The public examination took place at the Leeds Bankruptcy Court on Tuesday of Harry Austin and James Myers, trading as Austin and Myers, manufacturing electricians and electrical engineers, Armley, Leeds. The liabilities were £261. 18s. 11d., and the assets £79. 4s. 6d., the debtors attributing their failure to "losses by bad debts and expenses of advertising." It was stated that at a private meeting of creditors an offer of 5s. in the £ was made, but it was not accepted, and the petition was accordingly filed. The examination was closed.

SHOP LIGHTING.—The last issue of the *Warehouseman and Draper* contains an article contrasting the electric light with gas for shop lighting, in the course of which it remarks that, with respect to efficiency, economy, health, and safety, there can be no doubt that, "in at least three out of the four points, the electric light is far and away superior to gas."

TRADE JOURNALISM.—The publishers of the *Paper Maker* have just issued what they term "a special World's number" of that journal, containing specially-written articles on the subjects of paper making and paper-making machinery. The number is admirably got up, and any of our readers taking an interest in the subject will find much to instruct them in this special issue, which is price 2s.

THEATROPHONES.—The National Telephone Company have fixed a set of theatrophones by which the entertainment at the Empire Music Hall, Cardiff, can be heard at the Panopticon in that town, and at the recently opened exhibition at Bristol.

THE CONTRACT FOR STORAGE BATTERIES FOR ST. PANCRAS.—We understand that the above contract was not, as its title would indicate, entirely for storage batteries, the greater portion being for instruments, cables, and motor transformers. As is well known throughout the trade, the Electrical Power Storage Company confines its business entirely to the manufacture of storage batteries and the more immediate accessories therefor; they were accordingly not able to tender directly on the terms of the specification. Would it not be as well for electrical engineers when drawing up specifications to bear in mind that some portions of the plant may be of such special character as to necessitate the subdivision of the contract. There is scarcely a single firm in the country which can supply all the above collection of apparatus from its own shops. Both cable making and storage batteries are essentially special articles of manufacture.

MESSRS. RICHARD HORNSBY AND SONS (LIMITED).—This firm have commenced to make water-tube boilers under the patents of the Mills Patent Sectional Boiler Company, and will in future carry on the manufacture of these boilers under the title of the "Hornsby" Water-Tube Boilers, which are made with patent water-lined furnaces (single and double flues) for bituminous and smoky coal, and with large brick-lined furnaces for inferior and bulky fuel, or for any fuel requiring large grate area. As the boilers can be handled in sections where transport is difficult, they are specially adapted for export. Messrs. Hornsby have put down for the Manchester Corporation, at their central electric lighting station, six vertical compound tandem condensing steam engines, which, we learn, are giving every satisfaction. The firm have lately been busy supplying a large number of engines for electric lighting purposes in various parts of the world.

WATERHOUSE ELECTRICAL MANUFACTURING COMPANY (LIMITED). This Company have completed, and are prepared to supply, a new alternating arc lamp, which, we are informed, at a recent test on a tension of 60 volts, gave excellent results. The Company are

Digitized by Google

issuing a price list and a description of the Waterhouse arc lamp, giving full illustrated details. This list is of a handy pocket size, and can be obtained on application at the Company's works, 67, Southwark Bridge-road, S.E., or at the offices, 33, Old Broad-street, E.C.

TELEGRAPHIC ADDRESSES.—Mr. H. Sell, of Fleet-street, London, E.C., announces that he has obtained the permission of the Postal authorities to publish a complete official list of registered telegraphic addresses. This Directory is, we understand, to be published annually, with quarterly supplements.

THE "ENGINEERING MAGAZINE."—The September number of the *Engineering Magazine* contains articles on "Some Facts about the Silver Industry," by Albert Williams, jun.; "A Scientific Analysis of Money," by Emil Schalk, C.E.; "Steamboating in the West and South," by Walker Kennedy; "Growth of Commerce on the Lakes," by H. C. Pearson; "The Need of Uniform Building Laws," by Wm. J. Fryer; "Nickel-Steel Armour-Plate for the Navy," by R. B. Dashiell, U.S.N.; "Electricity and Electric Generators," by Horace F. Parshall; "Distance and Railway Tariffs," by James L. Cowles; and the usual Editorial Departments. Many of the articles are accompanied by high-class illustrations of the character familiar to readers of the magazine.

BELFAST.—At the last meeting of the City Council Mr. Barklie complained that they were without information regarding the progress of the electric light works, and he would like to know if these works had been abandoned. Mr. Young, in reply, said that some premises recommended by Prof. Kennedy had been taken for the purposes of the electric lighting station, and there was only a question in regard to title to be settled.

BLACKPOOL.—The current from the new central station in Princess-street was turned on for the first time on Thursday last week to some private consumers, and it is expected that in the course of the next few days the entire installation of public and private lighting will be completed and at work. The electric tramways are at present worked from a separate installation in Princess-street, but it is now proposed to produce the current for both tramway and illuminating purposes at the one central station, and it is probable, therefore, that within a short time two more engines and dynamos will be put down at the new works.

BOURNEMOUTH AND POOLE.—An exhibition has just been opened at Bournemouth in which an installation of electric cooking, &c., is on view, under the superintendence of Mr. E. R. Dale, who has also charge of a similar installation at an exhibition to be opened at Poole (Dorset).

BRIGHTON.—The masonic rooms at the Pavilion are in future to be lighted by electricity.

CAPE TOWN.—It will be remembered that the Town Council in November last accepted the tender of Messrs. Siemens and Halske for a system of electric lighting for the city. The installation is to be completed by the end of 1894, and we learn from Cape journals just to hand that the construction of the necessary buildings had been commenced.

CLERKENWELL.—The Vestry, on Thursday, refused to accede to a request from Mr. Sydney Morse that they consent to an extension of time till the beginning of next year for carrying out the County of London Electric Lighting Provisional Order.

DUNDEE.—The Lighting Committee of the Police Commission are about to hold a special meeting to consider the advisability of increasing the number of public thoroughfares to be lighted by electricity. Some 40 additional lamps would be required, entailing a cost of about £800 for their erection and maintenance.

FALMOUTH.—The Urban Sanitary Authority at their last meeting directed the Lighting Committee to obtain a report as to the probable cost of lighting the main streets by electricity.

HOLBORN.—At the conclusion of the business at the meeting of the Holborn Board of Works at the Town Hall on Monday, the Chairman (Mr. Phillips) at the request of the members switched on the electric light, which has been installed at a cost of over £400, to the large hall and committee room. The light was both clear and brilliant, and all admitted it to be a great improvement on the old illumination by gas. Messrs. Verity and Sons, of Covent-garden, were the contractors for the work, which was carried out under the supervision of Mr. John Dyer, the firm's foreman.

HULL.—In connection with the extension of the electric lighting scheme outside the old town, the current was turned on to consumers for the first time last week.

KENDAL.—A motion had been placed on the agenda paper for consideration at the meeting of the Town Council last week, that a committee be appointed to consider the expediency of the Corporation applying for a Provisional Order empowering them to supply the electric light within the Borough, but the matter was deferred until the next meeting.

KINGSTON-ON-THAMES.—As far as the bricks and mortar are concerned, the construction of the central station may be considered as practically finished. The two large boilers, which have been supplied by Messrs. G. E. Belliss and Co. (Limited), have been fixed, and the machinery in being rapidly placed in position.

LAMBETH.—The Board of Guardians had before them at their meeting last week the report, prepared by Mr. W. H. Preece, upon the proposal to light the Workhouse and Infirmary by electricity. After noting that the cost of gas for lighting purposes now amounted to about £1,500 per annum, Mr. Preece stated that, in his opinion, some 1,750 incandescent lamps of 16 c.p., or their equivalent, would be necessary to properly light the two buildings under consideration. To provide this light plant would be required, costing, in the first place, £6,900, and the working expenses and interest on capital would amount to about £1,850 per annum. Against the slightly increased cost must be put the value of the better lighting in the Infirmary, where the purer atmosphere would do much to aid the medical staff. After some discussion, the consideration of the matter was adjourned for a month in order that some further particulars might be obtained from Mr. Preece.

LYNTON.—At the last meeting of the Local Board it was stated that an iron framework had been fixed on the Rhine Tower at Lynmouth for a 2,000-c.p. arc light. Exception was taken to the appearance of the structure, and after discussion it was resolved that the Lighting Committee should arrange for a smaller light at the corner of the tower, and that the Trinity Brethren be informed that the proposed 2,000-c.p. light would not be installed.

MONMOUTH.—At a meeting of the Town Council on Monday a committee of five was appointed to inquire into the question of the purification of the river, and to endeavour to ascertain if sufficient water-power could be obtained for generating electricity for municipal purposes. A sum of £10 was voted for the purpose of obtaining the opinion of an electrical expert.

MORLEY.—At a meeting of the Town Council on Monday it was resolved, on the recommendation of the Electric Lighting Committee, to advertise for schemes to be submitted for the electric lighting of the Town Hall and the borough generally; the competitors to show in detail two schemes, one for the lighting of the Town Hall alone, and the other for the lighting of such parts of the borough as they might think could be profitably supplied with the electric light.

NEW ROMSEY.—There is an opportunity to introduce the electric light into New Romsey, where the Gas Company, owing to a dispute with the Corporation, have taken the gas lamps away. The Council have recently received tenders for lighting the town with oil, but would probably be open to a reasonable offer for the electric light.

PERTH.—The Town Council, at their meeting on Monday, refused to give their consent to an application by the Caledonian Electric Supply Company (Limited) to the Board of Trade for a Provisional Order authorising them to supply electric light to the burgh of Perth.

WORCESTER.—At the last meeting of the Board of Guardians it was moved that the resolution recently passed by the Board, adopting gas as the illuminant for the new workhouse, should be rescinded, and that electricity should be adopted instead. It was pointed out that as the Corporation had resolved to adopt electricity for the lighting of the city, it was the duty of the Guardians, in the interests of the ratepayers, to have the light which was supplied by the Corporation. The motion was, however, lost by a small majority.

WREXHAM.—At the last meeting of the Town Council a letter was read from the Board of Trade informing them that the proposed revocation of the Wrexham Electric Light and Power Order, 1890, had been postponed for one year from August 14th. A letter was read from Messrs. Lewis and Son, solicitors, stating that the Wrexham Electric Light and Power Company (Limited) were prepared, in accordance with the offer made by the Chairman of the Company to the Lighting Committee on April 25th, to sell the Company's Provisional Order for £500, and it was decided to call a special meeting of the Council in Committee to consider the question.

COMPANIES' MEETINGS AND REPORTS.

Direct Spanish Telegraph Company (Limited).

The fortieth ordinary general meeting of this Company was held at the offices of the Company, 280, Winchester House, Old Broad-street, London, E.C., on Friday, September 1, 1893, for the purpose of receiving the Directors' report and accounts, and for transacting the ordinary business of the Company; and notice was also given that immediately after the conclusion of the ordinary meeting an extraordinary general meeting of the Company would be held at the same place to supply the casual vacancy in the office of auditor, occasioned by the death of Mr. Herbert R. Duke. Sir John Pender, G.C.M.G., M.P. (Chairman of the Company), presided.

Mr. CH. GERHARDI (the Manager) read the notice calling the meeting and the minutes of the last meeting, which were confirmed and signed by the Chairman as a correct record.

The report of the Directors was taken as read.

The CHAIRMAN: Gentlemen, you have had the report in your hands for some time, and I presume you will agree to take it as read. A reference is made in the report to the death of Sir James Anderson (the late Chairman of this Company) in paragraph 5, which states:—"The Directors report with extreme regret the death of Sir James Anderson, who had been Chairman of the Board since 1884. At the invitation of the Directors, Sir John Pender, G.C.M.G., M.P., has joined the Board to fill up the vacancy." If you will allow me, I will refer to that first. Sir James Anderson, as you are aware, was the Managing Director of the Eastern Telegraph Company. He was a well-trusted and very efficient colleague in that Company, and when this Company became more related with the Eastern Telegraph Company, and with its wide and extensive system—the Eastern Company being one of the largest shareholders in this Company—it was suggested by myself that Sir James Anderson and my son should join the Board of the Company, and they did; and the result has been, I think, on the whole very successful for this Company. Now, in expressing regret at the loss of Sir James Anderson as a colleague and a friend, I am only saying that which I feel very deeply and very warmly. For 25 years we were more or less associated with the development of submarine telegraphy, and from his great nautical experience he was of value in every way, and I feel that he having passed away—and death has been rather strong upon us during the last six months, we having lost also our auditor—I feel that looking to the close relationship which existed betwixt the Eastern Company and this Company, that I being asked to take Sir James Anderson's place that the experience which we had gained together might be valuable it made available here, and therefore while deploring the loss of Sir James Anderson, and expressing regret at the death of a valued friend and colleague, I have also to thank the other gentlemen for the confidence they have placed in me in asking me to take the position which Sir James Anderson formerly held here. I did not take the position from love of more work, but from a desire to keep the great system of submarine telegraphy which has been more or less developed as one of the great works of the last 25 years—a work which probably has had more effect upon the political and commercial system of the world than anything else that has been done. I say my grave desire was to keep that system—I, and my colleagues—in a sound state, and to do everything in my power to carry on the great development of it during the next 25 years, although probably I shall not be present at the expiration of that time, but at all events I shall try to do as good work in the future as has been done in the past. And now, if you please, we will come to the general business of the day. You will see from the figures of the report, which you have before you, that the annexed accounts for the half-year ended June 30, 1893, show, after providing for debenture interest, a balance to the credit of profit and loss of £4,645. 13s. 9d. The traffic receipts show a decrease of £593. 8s. 9d. as compared with the corresponding period of 1892. The falling off in the receipts is chiefly due to the stagnation of Stock Exchange business in England, Spain, and France. It is not necessary for me to tell you that probably never in my recollection has there been a period of such intense depression of trade as has existed during the last six months, which we are now referring to, and I believe that those results which are somehow brought about by overtrading bring about eventually a more wholesome state of things, and I only hope that that will be the case in this instance. As you all know, telegraphy—submarine telegraphy—in every part of the world is now used in bad times as well as in good. It is a remarkable feature in submarine telegraphy during the last six months that when things were probably at their worst, submarine telegraph stocks, instead of going back went rather a little better. I feel that the development of submarine telegraphy can only be looked for through the development of commerce throughout the world. The working expenses are £130. 6s. 5d. in excess of those for the corresponding period of last year, and the increase in the working expenses is quite unavoidable, and is principally in the item of salaries and general expenses which cannot be regulated according to the number of telegrams conveyed. Stationery, on the other hand, which is used in proportion to the number of messages, shows a decrease. There is no falling off; in fact there is a slight increase in the traffic derived from other sources, viz., commercial and industrial. Every effort is being made to reduce expenditure, but it must be remembered that we cannot with safety make any serious reduction in our staff, as any sudden influx of business could not be efficiently met, some time being required to train operators for our particular work, and, as it will be seen by the accounts, the item of salaries and wages is the principal one in our expenses. Our working expenses will, however, compare favourably with those of other cable companies. I dare say that you will understand that when young men come to us they come at moderate salaries, and they meet with that interest and encouragement that every young man looks for when putting his foot upon the first rung of the ladder of life. Still, this is after all a comparatively small matter, and I think on the whole you will consider it satisfactory. The Company's cables and the land lines in connection with them have continued in good working order throughout the half-year. The other day, however, we had a breakdown, and that will be alluded to at the next meeting. I think I may say that that breakdown was probably one of the most rapid and prompt repairs ever made in connection with submarine telegraphy, as the ship left, mended the cable, and was back at London inside a week. After adding the usual sum of £2,500 to the reserve fund, the balance of profit and loss amounts to £2,145. 13s. 9d. To this the Directors propose to add £345. 0s. 10d. from interest on investments, and recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference shares, and a dividend at the rate of 4 per cent. per annum (free of income-tax) on the Ordinary shares. The reserve fund will then amount to £35,963. 11s. 3d. The rate of dividend on the Ordinary shares is the same as has been paid since July, 1891. The dividend warrants will be as usual issued on the October 2nd, the 1st being Sunday. Out of the reserve fund as it now stands, namely, £35,963. 11s. 3d., no less than £32,279. 18s. 5d.

Digitized by Google

are invested, yielding an average interest of nearly 3½ per cent. In the conduct of submarine telegraphy I find the bigger the reserve fund the more satisfactory it is to the shareholders generally. If we acted on the principle of dividing every shilling of the profits we had to divide amongst the shareholders the Company would not be anything like so valuable as it is to-day. A good efficient reserve fund is in my opinion the basis of success in submarine telegraphy. The traffic since July 1st last up to date is £275 short of that for the same period of 1892. This is still partly owing to the absence of Bourse traffic. As you know, that traffic has a wonderful effect upon our returns, and if any of the gentlemen I am addressing now know anything of the Stock Exchange they will know that it has not been particularly lively or particularly profitable during the past six months; and as far as that department of our business goes we have, more or less, suffered. At the same time, however, it is comparatively a small sum, and I hope the dark times are passing away, and they will be replaced by brighter ones. We have now had a considerable period of depression, and I hope it has brought about a purification of the commercial atmosphere, and we shall now have a brighter and more prosperous time in trade, and if we have that you may depend that submarine telegraphy will follow. I will now move—

"*That the report and accounts now submitted be and the same are hereby received and adopted.*"

Mr. E. ETLINGER: I beg to second that.

There being no questions, the resolution was put and carried unanimously.

The CHAIRMAN then moved, and Mr. JOHN D. PENDER seconded—

"*That the dividend at the rate of 10 per cent. per annum (less income-tax) on the Preference shares, and a dividend at the rate of 4 per cent. per annum (free of income-tax), on the Ordinary shares, both for the half-year ended June 30, 1893, be and are hereby declared.*"

The motion was carried.

The CHAIRMAN: That is the business, gentlemen, of the ordinary meeting. The extraordinary meeting will now be held. Will any shareholder be kind enough to move this resolution, as it is one for election of the Auditor, and should come from that side of the table.

Mr. W. HIBBERDINE: I have much pleasure in moving—

"*That Messrs. Deloitte, Dever, Griffiths and Co. be and are hereby elected auditors to the Company for the current year with a fee of 30 guineas, in the place of Mr. Herbert R. Duke, deceased.*"

Mr. WEST seconded the resolution, which was agreed to without discussion.

The CHAIRMAN: The firm of Messrs. Deloitte, Dever, Griffiths and Co. is a firm of accountants well known in London, and they are responsible to you for the accounts which they pass. They are appointed by you, and, as far as we can say, having known them for a number of years, they know a great deal about their business, and I can say myself that they are fully entitled to the confidence you have placed in them.

Mr. WEST: I should like to propose a vote of thanks to the Chairman and Directors for the great trouble and anxiety they have experienced during these troublous times, and for looking after the business of the Company in the manner in which they have. I have known Sir John Pender for a great many years, and have always attended these meetings, and I may say that I always feel safe when I have a little money in telegraph shares.

Mr. CREASEY seconded the resolution, which was agreed to.

The CHAIRMAN: Gentlemen, I thank you on behalf of my colleagues and myself for the vote which you have passed. The work that has been done in looking after this telegraph system has sometimes been of a very complicated nature, and has required very prompt attention. There is, however, something of the *esprit de corps* in this Company which helps us to feel that we have a great interest to represent and a great position to maintain; and it is our duty and pleasure to strengthen that position every way by every means in our power. I thank you for the compliment which you have done us.

The proceedings then terminated.

NEW COMPANIES, STATUTORY RETURNS, &c.

[In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1893, pages 320-348, &c., &c.]

DOLGOROUKY COPPER MINES AND SMELTING COMPANY (LIMITED).—This Company has been registered with a capital of £210,000, in £1 shares, to carry on business as copper miners and smelters, mechanical and electrical engineers, machinists, wire drawers, tube makers, metallurgists, &c.

BRITISH VOLTA ELECTRIC GLOW-LAMP COMPANY (LIMITED).—This Company was registered on August 31st, with a capital of £2,000, in £1 shares, to manufacture, sell, and deal in incandescent electric lamps, and telegraphic, telephonic, and electric apparatus and appliances generally, to construct, lay down, fix, carry out, establish, work, manage, control, regulate, and deal in all necessary works, cables, wires, accumulators, lamps, apparatus, appliances, and conveniences for the transmission and facilitation of telegraphic and telephonic communications and messages, and for the lighting of towns, streets, building and places (public and private), and generally to carry on the business of supplying electricity. The subscribers are:—

	Shares.
A. T. Turney, Berghill-road, Sydenham, electrical engineer ...	1
G. White, Great Missenden, Bucks	1
E. C. Lacey, 121, Knight's-hill, West Norwood	1
G. Willard, 47, Forest-lane, Stratford, E., electrician	1
W. Habgood, 49, Queen Victoria-street, E.C., electrical engineer	1
H. Foster, 87, Grange-road, Bermondsey	1
W. C. Stembridge, Iliffe-street, Kennington Park-road, S.E....	1

RAILWAY ELECTRICAL FOG SIGNAL SYNDICATE (LIMITED).—The statutory return of this Company, made up to March 26, 1892, was not filed until July 19, 1893, when out of a nominal capital of £25,000, in £1 shares, 18,000 had been taken up, all of which were issued as fully paid in consideration for the patents and business acquired by the Company. The 1893 return was filed last March.

READING ELECTRIC SUPPLY COMPANY (LIMITED).—No business has yet been done by this Company, as is seen by the last return filed on August 31, 1893, which shows that the seven signatories' shares are the only ones taken up out of a nominal capital of £75,000, in £5 shares.

SAXBY AND FARMER (LIMITED).—The statutory return of this Company, made up to August 28th, has been filed. The nominal capital is £25,000, in £10 shares, of which 2,021 have been taken up, 1,800 have been issued as fully paid, and the full amount has been called and paid on the remaining 221 shares.

SHROPSHIRE ELECTRIC LIGHT AND POWER COMPANY (LIMITED).—The first annual return of this Company, made up to June 14, 1892, was filed on August 1, 1893. The nominal capital is £25,100, divided into 2,500 Ordinary shares of £10 each, and 100 Founders' shares of £1 each. 275 Ordinary and 44 Founders' shares have been taken up, and a call of 5s. per share called on the former class, while no calls have yet been made on the £1 shares. The shareholders have paid on allotment £595. 5s., leaving £22. 10s. due. The third annual return, made up to June 14, 1893, and also filed on August 1st, shows no alteration in the above figures.

VEALE AND CO. (LIMITED).—An agreement, dated May 17, 1893 (filed June 16th following) between John E. Veale, of St. Austell, Cornwall, electrical engineer (referred to as the vendor), of the one part, and the above-named Company, of the other part, provides for the sale to the Company of the business of electrical engineer carried on by the vendor at St. Austell, Cornwall, and the transfer of the electric lighting undertaking for the Local Board district of the parish of St. Austell for £3,939. 18s. 6d. The vendor has advanced certain sums of money to the Company, amounting in all to £805. 12s. 10d., and the whole (including the purchase consideration) will be fully satisfied by the allotment of 4,644 fully-paid shares, Nos. 4,905 to 9,548 inclusive.

CITY NOTES, &c.

AN AMERICAN ELECTRIC RAILROAD IN DIFFICULTIES.—The Sandusky, Milan, and Huron Electric Railroad has been placed in the hands of J. C. Gilchrist, of Vermilion, as receiver. The road is one of the largest electric lines in the country. The failure of Cleveland capitalists to take $75,000 of the Company's bonds, as promised, embarrassed it to such an extent that it could not meet the demands of creditors, and the receivership is the result.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended September 3rd were £745, as against £737 for the corresponding period of last year, being an increase of £8. The total receipts for the half-year amount to £7,373, against £6,927 in the corresponding period of 1892, being an increase of £446.

CUBA SUBMARINE TELEGRAPH COMPANY (LIMITED).—The estimated traffic receipts of this Company for the month of August are £3,000, as compared with £3,166 in the corresponding month of last year.

DIRECT SPANISH TELEGRAPH COMPANY.—The gross receipts for the month of August were £1,670, as compared with £1,884 for the corresponding period of last year.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announce the opening of a branch office at Winchester House, Old Broad-Street, E.C. for the acceptance of telegrams for South America, South Africa, Egypt, India, China, Australasia, &c.——The Company also notifies that the Brazilian Government having suspended their International telegraph service, messages for that country cannot at present be accepted. Telegrams for Uruguay, Argentina, &c., can be accepted as usual.——The traffic receipts for the month of August amounted to £51,991, and to £49,069, in the corresponding period of 1892, an increase of £2,922.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY (LIMITED).—The traffic receipts of the Eastern Extension, Australasia and China Telegraph Company (Limited) for the month of August, 1893, amounted to £41,791 and to £42,035 in the corresponding period of 1892; decrease, £244.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this Company for August amounted to £23,200, and from January 1st to August 31st to £180,000. In the corresponding months of 1891 and 1892 the amounts were £189,400 and £175,600 respectively.

Digitized by Google

WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED.)—The receipts of this Company for the two weeks ended August 31st were £1,732, as compared with £1,938 for the corresponding period of last year.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended September 1, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £2,725.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 800.—Vol. XXXI. FRIDAY, SEPTEMBER 15, 1893. PRICE FOURPENCE. *Annual Subscription (U.K.), 19/6*

NOTES.

The Presidential Address delivered before Section A of the ritish Association yesterday by Mr. Glazebrook dealt for e most part with the history of the undulatory theory of ght. Little did Hooke, Newton, Huygens, Fresnel, and en Cauchy, think that in studying the phenomena of optics, nd in building up a theory of light, they were laying the undations for a far wider theory—the theory of the ether—medium for the transmission, not only of light and radiant eat, but of all electric and magnetic forces. The electrical ngineer is perfectly justified in retaining for the present, and rhaps for many years to come, the idea of a current, and of ssuming that it flows along a wire. He may be allowed also talk of transmitting energy through a wire, like water rough a pipe, although he knows that the current is only one ctor of energy, and that he does not "transmit" the other ctor, difference of potential, along with it in the same wire. ut those who care to make a better acquaintance with elec-ical science than is needful for designing a dynamo or work-g a cable, must face the ether theory. Additions are being ade to it year by year, and the student may well be per-exed as to the point at which he should commence to study . He certainly cannot plunge at once into Lord Kelvin's ypotheses, nor are Maxwell's equations intelligible without a evious acquaintance with optics. Mr. Glazebrook's Address aces the gradual development of the whole subject, and while me of the purely optical portions have been omitted, our stract will be found to contain all that concerns the electrical pect of this important subject.

An abstract of a further communication by Profs. Dewar nd Fleming to the *Philosophical Magazine* on "The Electrical esistance of Metals and Alloys," will be found in another lumn. The results of this very important research were ven in the form of Tables and on a large chart. We have itted most of the former, and in reproducing the latter we ve left out curves relating to platinum-silver, nickel-steel, atinum-rhodium, and thallium, these being uncommon etals. The resistance of these are all greater than nickel. e have omitted tin, palladium, cadmium, magnesium, and rious alloys, in order to avoid the crowding together of es on our reduced diagram. The greater curvature of the es of the magnetic metals than of the non-magnetic is rthy of notice.

Nearly a year ago we reprinted from the *Philosophical Magazine* the first communication by Profs. Dewar and Fleming on this subject. The authors published no diagrams, and we prepared three sets of curves from their tables. In each of these we gave a line representing absolute zero, – 274°C. In preparing the present diagram we have ventured to repeat this feature. But it will be seen that there is a discrepancy between the intersection of this line and of the platinum line with the axis of temperature. This discrepancy, however, is not without interest. The line is accurately placed at – 274deg. on the horizontal scale. But the authors explain that this scale is a convention, and they call it a scale of platinum degrees—that is, the platinum line is assumed to be a straight line. If the scale of the air thermometer had been employed for the higher temperatures, and had been extrapolated in a straight line for lower temperatures, the platinum line would be slightly curved. Mr. Callendar has shown that the difference from a straight line is nearly a parabolic function of the air thermometer temperature. This curved line would cut the straight line at two points, and at two only. Profs. Dewar and Fleming have provisionally chosen the two arbitrary points of 0°C. and 100°C., so there can be no coincidence at – 274deg., hence the discrepancy in our diagram, which thus shows very clearly the relation between the two scales. The platinum line being drawn straight by convention, the air line would be curved, starting from – 274deg. to the intersection of the platinum line with with 0deg., then crossing the platinum line, rising above it, and recrossing it at 100°C. The difference would for the most part be less than the thickness of the platinum line in our diagram.

That somewhat anomalous mode of acquiring knowledge of certain "useful" branches of natural science, which is commonly called technical education, has been discussed on many occasions in these columns. We have lamented its tendencies, and have called attention to the mischief which may arise if professors continue to attempt to teach details of engineering practice instead of confining themselves to the principles on which these details are based. It is unnecessary again to dwell at length on this subject, but we cannot allow Prof. Jamieson's Paper read at the Chicago Congress to pass without a protest. This Paper, entitled "London Electrical Engineering Laboratories," consists of three sections: I. Advantages of College laboratories and workshops; II. Should a college training precede, be combined with, or follow an

Digitized by Google

apprenticeship? III. London electrical engineering laboratories. Early in the first section the author says, "it is possible to teach students how to turn, file, fit, and solder metals, how to joint wires and cables for telegraph, telephone, and electric light circuits. . . ." Possible, indeed! but to eight students out of ten, mere trifling, and perhaps to be afterwards unlearned. It would be "possible," indeed, for the foreman of an erecting shop to "teach" pupils the principles of thermodynamics, kinematics of machinery, theory of elasticity and strength of structures, to say nothing of the doctrine of armature reactions—after a fashion. Elsewhere in this section Prof. JAMIESON speaks of instructing students "in their everyday working details." Students who cannot afford to go through a proper course of physics must be content with useful bits of mechanics and electricity, but they should be studied as physics. Steam engines, boilers, dynamos, secondary batteries, and so on, should be used as laboratory instruments.

PROF. JAMIESON throws out several suggestions in connection with his second section, but answers the question by settling each case on its merits, which is no doubt satisfactory for the students, but does not give much information to outsiders. The third section, which gives the title to the Paper, appears to be based on a fortnight's visit to London, but Prof. JAMIESON could have written four-fifths of it from general knowledge. It is a pity that the admirable work of the technological or trade classes at Finsbury should be mixed up with the so-called technical education. Prof. JAMIESON speaks of two distinct sections, but does not sufficiently point out their different aims. "We must not forget to mention the Royal College of Science, . . . although the laboratory there is more of the nature of the Kelvin laboratory, . . . yet some very original, interesting, and instructive researches have been carried out in it by Prof. Boys, which have been of great use to electrical engineers." What a noble aim for Prof. Boys! How eagerly they await the results of his next research and wonder if it will be patented!

AFTER this the author gives a few details about institutions which he is able to appreciate, and finishes with one of the questions given at an examination for the diploma of his own college :—

"Go to the Faraday Works, Govan, and there make a complete set of freehand sketches of a ship lighting plant. From your sketches make a set of finished drawings. Take indicated horse-power cards, brake horse-power, and electrical horse-power tests at the normal speed and power of the engine and dynamos. Find the mechanical efficiency of the engine, the electrical and commercial efficiency of the dynamo, and write a concise report upon the suitability of the plant for the work it will have to do. You can take five days to this question. You are permittted to consult any book, but you must state the name of the book and the page whereon you get the information."

A delightful task for some men; but how much real work would it take to knock the conceit out of most students who, having done all this to the satisfaction of their teacher, and having criticised the "suitability of the plant," have duly received, framed and glazed, their richly-deserved diploma?

AN interesting return called for by the House of Com... has just been issued showing the revenue, expenditure... net revenue of the Post Office from 1870 to the present ... and in a form which is both novel and instructive. T... period selected is that during which the telegraph servi... been an adjunct of the postal department, but the respe... figures for each of the two services are not shown sepa... and, indeed, we should be left in some uncertainty ... whether the return relates to purely postal business ... not for the, as we should suppose, impossibility of e... apportioning the expenditure between it and the t... business. Be that as it may, the various columns ... return afford striking evidence of the magnitude of th... and the economy with which it is conducted by the ... Office. In these twenty-three years the revenue has ... than doubled, notwithstanding the many concessions ma... its customers in the way of cheapening the service since ... the still greater concessions to its servants in the shap... increased wages, yet the percentage of expenditure to rev... remains pretty much the same as it was. Salaries, s... annuation, and expenditure on buildings have increa... enormously—the percentage of the first-named alone to ... revenue having risen from 25·44 to 39·52. These additional expenses of management are partly counterbalanced, however, by reduced cost of conveying mails and of the tele... service. One notable feature of the return is that the ... revenue is shown after allowing for sites and buildings. ... the same principle the telegraphs would be entitled to cla... poles and wires in mitigation of net losses.

WE regret to record a fatal accident due to a shock fro... the 2,400 volt mains of the London Electric Supply Corpo... tion. On Tuesday last two men, ROBERT BALL and EDW... MEECH were at work in the Blackfriars sub-station. Th... are two sets of transformers stepping down from 10,000 vo... to 2,400 volts. Switches are arranged by which the secondary circuits of either or both sets of transformers can be connected to omnibus bars. The sets are alternately changed over for cleaning and examination, and in order to maintain continuity of supply, both sets are run in parallel for a time. With the intention of cleaning one of the sets which had been in ... the other was switched on, but by pure inadvertence the first one was not switched off. MEECH began to clean the fir... thinking they had been cut out of the circuit, when he received a severe shock. BALL pulled him off from the ... and apparently received a shock. Strange to say, Mr. ... though badly burned, recovered and found BALL dead, ... head wounded, apparently by falling back against a plank. MEECH is at St. Thomas's Hospital and is doing well, but we give little information about the accident.

ATTENTION will, of course, be paid to the prevention of su... an occurrence in future. Alternate blocking of the switches will not suffice, as both sets are run in parallel in switching over and during heavy loads. A partition or barrier with gate mechanically locked by a switch seems to meet the ... but the staff of the London Electric Supply Company will ...

Digitized by Google

ɔubt, be able to devise an efficient arrangement. This is the ɔcond time in this country that a workman engaged in his ork on high-pressure conductors has received a fatal shock. n each case, the only protection has been a rule, the lives ave been forfeited by breaking the rule. In each case the ct was deliberate. Other accidents, not from fatal shocks, ut from falls, death being indirectly due to the shock, have kewise been due to non-observance of regulations.

Personal.—Mr. G. R. Neilson has been appointed Secretary ɔf the Europe and Azores Telegraph Company.

The Canadian Electrical Exhibition.—This Association met n Toronto on Tuesday, Wednesday, and Friday of this week.

Brighton.—The arc lights on the sea-front are to be switched ɔn to-morrow evening. The lamps are to be run off the private ɔupply mains.

Cable Interruptions and Repairs.—

	Dates of Interruptions.	Date of Repair.
Aden–Zanzibar	August 9th	September 9th.
Pernambuco—Ceara	September 1st	—

Proposed Electric Tramways at Halifax.—The proposal of ɔome electrical tramway promoters to introduce the overhead ɔrolly system into Halifax was c« nsidered at a meeting of the Town Council on Tuesday, and a resolution that the question ɔf constructing tramways should be adjourned *sine die* was ɔarried.

The Electric Light at the British Museum.—On Wednesday ɔvening last week for the first time the desks in the large ɔeading-room of the British Museum were lighted by nearly 200 115-volt 16-c.p. glow lamps. The large 30 ampere arcs have been replaced by Siemens band lamps, taking about 20 amperes.

Glasgow and West of Scotland Technical College.—The ɔession of this College commences on Monday, October 2nd. Information and syllabuses of the courses on engineering and other departments of applied and general sciences may be obtained from the Secretary. Further information will be found in our advertisement columns.

The Five-Wire System for Rotterdam.—Messrs. Siemens and Halske have obtained the contract for the Rotterdam Electricity Works, which are to form a municipal electric light and power supply system. The five-wire direct current system is to be used. Two sub-stations, about a mile and a mile and a-half respectively from the central station, supply the town light and power.

The Hague.—The Siemens and Halske station at the Hague, which was laid down in 1889, has ever since been undergoing constant extensions. The last additions to the plant comprise two interior pole 160 kilowatt machines, coupled direct to Storck engines, and a battery of 286 ampere-hour accumulators. The total plant capacity of this station now amounts to 1,000 H.P., of which the accumulators can supply 100 H.P.

Gas and Electric Light Companies in France.—A break has occurred at Compiègne in the judicial successes hitherto scored in France by the gas companies. The local gas company brought the usual action against the electric lighting company for infringing the monopoly given to it by its concession from the municipality. The Courts, however, held that the gas Company's monopoly related only to gas lighting.

Bristol University College.—The courses of lectures and laboratory instruction in electrical engineering, under Profs. Ryan and Chattock, will commence at this college on October 5th. These courses are arranged to extend over a period of three years, and arrangements can be made for students to spend the summer months in engineering workshops. A considerable number of engineering scholarships are attached to this college.

Telegraphic Communication with South America.—The Western Brazilian Telegraph Company notify that the telegraphic route to South America, owned by this Company, is completely opened, so far as messages to the River Plate are concerned. The notification by the Brazilian Government of the closing of traffic to Brazil, of course, only refers to the traffic intended for that country, transit messages to Monte Video and Buenos Ayres being in no way affected.

St. Pancras.—The St. Pancras Vestry, acting upon the advice of Prof. Henry Robinson, have authorised extensions of their electric lighting installation by the addition of three 90-unit engines and dynamos and three boilers at the existing Regent's Park station with another sub-station in Regent's Park-road. These extensions will enable a further 5,000 16-c.p. lamps installed to be served. The Vestry have also decided to construct a second electric lighting station in combination with a refuse destructor in King's-road.

The German Union of Electrical Engineers.—The annual meeting of this union, says *Industries and Iron*, is to be held at Cologne on the 27th, 28th, 29th, and 30th inst. Among the Papers to be read are the following:—"Impressions of the Chicago Exhibition and the Electrical Congress," by Dr. Budde; "On a System of Measurements for Central Electric Stations," by Dr. Kallmann; "Charging Accumulators by Means of Alternating-Current Machines," by Herr Pollak; "On the Development of House and Private Telegraphs and Telephones in connection with the Imperial Post," by Dr. Sack; and "On a New Insulation Testing Set, and an Incandescent Lamp Resistance," by Prof. Dr. Heim.

The Clark Standard Cell.—A Correction.—We have received the following note from Dr. K. Kahle with reference to an unfortunate error which crept into our translation of his memorandum on the preparation of the Clark standard cell:—"In the translation of my Paper, 'Instructions for Preparing Clark Standard Cells' (*Electrician*, July 7th, p. 265), I have just seen that there is an error. In describing the preparation of the sulphate of mercury you mention a solution of one part '*mercuric sulphate*' to 1,000 parts of water; it should be a solution of one part '*sulphuric acid*' to 1,000 parts of water, as is written in the original. I hope you will be so kind as to correct this in your journal."

List of the Official Delegates at the Chicago Congress.—The following is a complete list of the official delegates at the recent International Electrical Congress at Chicago:—*England*, Profs. Ayrton and Silvanus Thompson, Major-Gen. C. E. Webber, Mr. W. H. Preece, and Mr. Alexander Siemens; *United States*, Profs. H. A. Rowland, H. S. Carhart, T. C. Mendenhall, E. L. Nichols, and Elihu Thomson; *France*, MM. Hospitalier, Mascart, De la Touanne, Violle, and Dr. S. Leduc; *Germany*, Prof. von Helmholtz, Dr. Emil Budde, Dr. Otto Lummer, Herr Schnaeder, and Prof. Voigt; *Italy*, Prof. Galileo Ferraris; *Austria*, Dr. J. Sahulka; *Switzerland*, Dr. A. Palaz, Prof. Réné Thury, and Prof. Weber; *Sweden*, M. Wennmann; *Mexico*, Senor Don A. M. Chavez; *British North America*, Mr. Arthur Higman.

Charterhouse Science and Art Schools and Literary Institution.—The winter session of this, one of the largest science and art schools in the United Kingdom, will commence on Saturday, September 23, 1893, under the Presidency of the Rev. H. Swann, M.A. During the late session upwards of 300 students, mostly elementary teachers, availed themselves of the privileges afforded by this Institute, and a large number presented themselves for examination, and were successful in obtaining advanced certificates, and also a fair number of honors awarded by the Science and Art Department of South Kensington. The grants earned by the students were far in excess of those of any previous year. Instruction of a practical character is given in most of the sciences at a nominal fee; and in art at an equally low rate. Students under the direction of many competent instructors can be advanced in their studies.

Electrical Communication with Lighthouses.—In a supplementary estimate recently issued, £10,000 is required for carrying out works recommended by the Royal Commission on Electrical Communication with Lighthouses. In connection with this, the President of the Board of Trade stated in the House of Commons last week that the work of connecting the Kentish Knock light-vessel with the shore by

Digitized by Google

telephone was now in progress. Lundy Island had been connected. Either the Tuskar or Gunfleet light would be put in hand at once, and the Chancellor of the Exchequer had also authorised the connection of the Goodwin (North Sand Head) light-vessel. All the shore lighthouses recommended, except that at the Needles, which was now in hand, had been already telephonically connected with the land. The experiment of connecting the Fastnet lighthouse with Crookhaven by a non-continuous cable had not yet been carried out.

The Telegraph in the Field.—The part likely to be played in any future war by the military telegraphs is admirably brought out by *The Times* correspondent, present at the autumn manœuvres. Referring to some clever manœuvring, the correspondent remarks:—"The situation when the telegraph was utilised was almost identical with that on the left flank of the French at Worth at 10:30 a.m. on August 6, 1870. In 1870 Von Kirchbach, attacking in front, had no wire connecting him with the Bavarians out of his sight on his right flank, and consequently the attack was isolated, involving failure and the unnecessary loss of thousands of lives. Now science has provided the connection; and from two different points of the compass forces can advance in absolute and methodical combination, and, acting together, accomplish their task successfully. The Royal Engineer Telegraph Battalion may fairly be credited with no small share in the crushing blow inflicted on the enemy's left flank at the battle of Seven Barrows."

Police Telephones.—The following paragraph from the *Essex County Chronicle* is typical of the present chaos in matters telephonic. At the last meeting of the Standing Joint Committee of the Essex County Council:—"The Clerk reported numerous difficulties which stood in the way of carrying out the tender of the National Telephone Company for the construction of telephonic communication for the police between Chelmsford, Brentwood, Romford, and London. The Romford Local Board wanted the wires underground, the Chelmsford Town Council wished to see the plans before giving any sanction to the scheme, while the Telephone Company stated that their tender, which was £121. 10s. per annum, was for the erection of poles and wires, and did not include the cost of any underground work."—Capt. Showers recommended that the tender of the Post Office for the establishment of the required communication be accepted at a cost of £135 per annum.—The recommendation was agreed to.

The Antwerp Electro-Hydraulic Scheme.—The scheme of combined hydraulic and electric distribution inaugurated at Antwerp by M. Van Rysselberghe is, we believe, to go forward notwithstanding the untimely death of its progenitor, and the following particulars relating to it may, therefore, be of interest. The agreement with the Antwerp municipality stipulates for the laying down of at least 8 kilometres of hydraulic and 16 kilometres of electric mains, to begin with; the resistance of the electric mains not to exceed 0·2 ohm per kilometre. The first hydraulic station is to be of about 500 H.P., and capable of sending 75 litres (15 gallons) of water per second into the mains at a pressure of 52·5 atmospheres (776lb. to the sq. in., or 1,785ft. head). In justifying his scheme before the municipal authorities M. Van Rysselberghe argued that 12 16-c.p. lamps could be obtained for the expenditure of one horse-power, and as one horse-power hour could be obtained from 2⅗lb. of coal the *coal* bill for one 16-c.p. lamp for one hour only came to 0·0125d., whilst the gas for a burner giving the same light cost ½d. an hour with gas at 5s. a thousand. Why is it, then, said M Van Rysselberghe, that electricians cannot undersell gas? Because of the loss in transmission to the consumer. Get rid of this loss, argued M. Van Rysselberghe, and we shall see what we shall see. This argument, although it did not take into account a source of loss which has made itself painfully evident in this country, namely, the loss caused by an irregular demand, convinced the Antwerp municipality, and M. Van Rysselberghe was given a concession for an hydraulic power station which is to transmit power by high-pressure water to turbines driving dynamos placed in small sub-stations and feeding into a low-pressure two-wire network; hydraulic power is also to be supplied direct to lifts, &c. Electricity is to be sold at a maximum price of 8d. per kilowatt hour, and water-power at 4½d. the cubic metre under a minimum pressure of 47½ atmospheres.

Technical Instruction.—A Parliamentary paper just published gives an abstract of returns furnished to the Department of Science and Art, showing the manner in which, and the extent to which, technical instruction is being fostered by local authorities. The returns were made in response to a letter sent to them last Session by the Education Department. Of the 49 counties in England, 42 apply the whole amount of the residue received under the Local Taxation (Customs and Excise) Act, 1890, to technical education, and the remaining 7 apply a part of the residue. Of the 61 county boroughs, 47 apply the whole and 10 part of the residue. Of the 13 counties in Wales (including Monmouth, to which the Welsh Intermediate Education Act, 1889, applies), 12 apply the whole and 1 a part of the residue, Six counties levy a rate or make grants out of the rates, under the Technical Instruction Act, 1889; and all 13 levy a rate under the Welsh Intermediate Education Act, 1889. The three county boroughs all apply the whole of the residue to technical education under the Welsh Intermediate Education Act, 1889, and levy a rate under the same Act, and one borough also levies a rate or makes grants out of the rates under the Technical Instruction Act, 1889. Of the 33 counties in Scotland 20 apply the whole of the residue to technical education, 6 apply a part, 4 are considering the question, and 2 apply the whole of the residue to the relief of the rates. Of 82 burghs, only 7 apply the whole to technical instruction, 21 a part, 1 was considering the question, 51 apply the whole residue to relief of the rates, and 2 made no returns. Of 105 police burghs, nine apply the whole to technical instruction, 18 a part, 9 were considering, and 66 apply the whole to the relief of rates.

Papers read at the Chicago Congress.—The following is a complete list of the papers actually read, or taken as read, at the recent International Electrical Congress at Chicago:—"On the Analytical Treatment of Alternating Currents," by Prof. A. Macfarlane, of Texas University; "Complex Quantities and their Application to Electrical Engineering," by Mr. C. P. Steinmetz; "General Discussion of the Current Flow in Two Mutually-Related Circuits containing Capacity," by Drs. Bedell and Crehore; "Explanation of the Ferranti Phenomenon," by Dr. Johann Sahulka, of the Technische Hochschule of Vienna; "Measuring the Power of Polyphase Currents," by A. Blondel; "Extended Use of the Name Resistance in Alternating-Current Problems," by Prof. W. E. Ayrton; "Transmission of Electrical Signals through Space," by Mr. W. H. Preece; "Ocean Telephony," by Prof. S. P. Thompson; "On the best Value for Resistance Coils," by Dr. Lindeck; "On the Temperature Coefficient of Copper," by Mr. A. E. Kennelly; "On Photometric Measurements," by Prof. Thomas; "On Electrostatic Voltmeters," by Prof. Carhart; "On a Method of Governing an Electric Motor for Chronographic Purposes," by Prof. Webster; "On Iron for Transformers," by Prof. Ewing; "London Electrical Engineering Laboratories," by Prof. Andrew Jamieson; "Transformer Diagrams Experimentally Determined," by Dr. Bedell; "On an Improved Instrument for Measuring Magnetic Reluctance," by Mr. A. E. Kennelly; "Variation of the Potential Difference of the Arc with Current, Size of Carbons, and Distance Apart," by Prof. W. E. Ayrton; "Light and Heat of the Arc," by M. Violle; "The Swinburne-Thompson Unit of Light," by Prof. S. P. Thompson; "Periodic Variation of the Candle-Power of Alternating Arc Lights," by Prof. B F. Thomas; "Maximum Efficiency of Arc Lamps with Constant Number of Watts," by Prof. Carhart; "On New Researches with the Alternating-Current Arc" and "On the Constant-Current Arc and its Employment as a Standard of Light," by M. Blondel; "Source and Effects of Harmonics," by Prof. Rowland; "Rotary Mercurial Air-Pumps," by Mr. F. Shulze-Berge; "Underground Electric Construction in the United States," by Prof. D. C. Jackson; "Various Uses of the Electrostatic Voltmeter," by Mr. F. Sahulka; "The New Incandescent Arc Light," by Prof. L. B. Marks; "On Direct-Current Dynamos of Very High Potential," by Prof. F. B. Crocker.

ELECTROMAGNETIC THEORY.—LIV.

BY OLIVER HEAVISIDE.

(Continued from page 439.)

§210. Although the equations connecting the voltage V and ,aussage C, through the line constants R, S, K, and L, are of , symmetrical character, so that, abstractedly considered, a tudy of the nature of their propagation on either side of the listortionless state is as desirable as on the other side; yet when we examine the conditions prevailing in practice, we see at once that one side only presents itself actively. The reason is easily to be seen. It is in all cases desired to get plenty of received current, because that is the working agent, and leakage is detrimental to this consummation. There are, besides, practical inconveniences connected with leakage. Thus it comes about that we are mainly concerned with the state of things existing when R/L is greater than, or at the least equal to K/S, and scarcely at all with the exceptional case of an excess of leakage, unless it be as a curiosity, and for the sake of its theoretical connection with other electromagnetic problems.

Now this concerns the propagation of V and C through the external dielectric. The influence of R prevails over that of K, and controls matters. It is, however, somewhat remarkable that the other side of the propagation problem does actually present itself actively, when we regard the important secondary effect of the propagation into the guides of the cylindrical waves, which result from the passage over them of the plane waves in the external dielectric. Suppose, for example, there is no external conductance. This gives one extreme form of propagation of V and C, the quantity K/S (or equivalently k/c), being zero, and R/L finite. Now, remember that in the exact plane wave theory R stands for the magnetic conductance of the external medium, so that R/L is the same as g/μ, and therefore we are, when considering V and C, also discussing the influence upon the plane waves of the fictitious property of magnetic conductance.

On the other hand, in the guides themselves, which are electrical conductors, and perhaps, and most probably, dielectrics as well, it is k/c that is greater than g/μ, since the latter is zero. Here, then, we have the other extreme form of the theory. In the external dielectric k/c is zero and g/μ (equivalent to R/L) finite, whereas in the guides is zero and $g/\mu k/c$ finite. The distortion of the external plane waves by the resistance of the guides is, therefore, of the opposite kind to that of the cylindrical waves in the guides, for **E** and **H** change places when the form of the distortion is discussed.

Now, in the guides, on account of their being very good conductors, the permittivity is swamped, and it may be ignored in calculating resultant effects. Then we have the theory of pure diffusion (as of heat according to Fourier), controlled by the *two* constants k and μ, since both g and c are now zero. Similarly, in the external dielectric, it may happen that the influence of μ (or equivalently of L) is insensible, as in the slow working of long cables; then the propagation of V and C is controlled by the *two* constants g and c (or actually and equivalently by R and S), whilst the other two, k and μ, are zero. Here, then, we have a curious exchange of active properties between the dielectric and the conductor. In both, the resultant propagation follows the diffusion law, but is controlled by different properties. The propagation of V or **E** outside is like that of **H** inside, and the propagation of C or **H** outside is like that of **E** inside.

We see by the above illustrations that in spite of the absence of magnetic conductivity in reality, we are, nevertheless, obliged to consider both sides of the wave-theory it involves, even in one and the same actual problem, provided it be treated comprehensively.

§211. As, however, we are not immediately concerned with the internal state of the guides, and, so to speak, eliminate them by treating R and L as constants, we may now dismiss their consideration, and return to V and C only, on our understanding that the quantity K/S is always less than R/L, or does not exceed it in the limit.

Now we have shown that the distortion in transit depends upon the difference

$$\sigma = \frac{R}{2L} - \frac{K}{2S}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

whilst the attenuation of the front of an advancing wave depends upon the sum

$$\rho = \frac{R}{2L} + \frac{K}{2S}. \quad . \quad . \quad . \quad . \quad . \quad (10)$$

Both σ and ρ should be as small as possible, of course. The four line-constants act upon ρ and σ in different ways, and it is rather important to understand them. So, remembering that the first term of the right members of (9) and (10) is bigger than the second, observe the effect of varying the line-constants, one at a time.

[R]. By increasing R we increase both ρ and σ. Thus the resistance of the guides is wholly prejudicial, since it not only weakens signals in transit, but distorts them. It is, therefore, a fundamental notion that the resistance of the guides should be reduced if possible, but never increased, if the object be to facilitate signalling.

[L]. By increasing L we decrease both ρ and σ. Thus the inductance of the circuit (other things being equal) is wholly beneficial, since it diminishes both the attenuation and the distortion in transit, or makes the received signals both larger and plainer. These are not necessarily insignificant effects, but may be very large when applied to very rapid vibrations on a long circuit

[K]. Increasing K increases ρ and reduces σ. Thus leakage is both beneficial and prejudicial, according to circumstances, since although it reduces the distortion, it simultaneously increases the attenuation in transit. This action is most pronounced when the signalling is slow.

[S]. Increasing S increases σ and reduces ρ. It may be, therefore, both prejudicial and beneficial. But practically the important effect of S, notably on cables, is the prejudicial one of distorting the signals, which is a large effect.

Now the above statements, though obviously true enough as deductions from (9) and (10), are merely qualitative. The practical import of varying one quantity when three others are constant, depends upon the actual immediate values of all four. The length of the line also comes in as an important factor, and likewise the frequency of the waves, to settle under what circumstances this or that variation of the line constants is important in a special case. Nevertheless, the above properties are important, and should be most usefully borne in mind in general reasoning, as well as in the detailed examination of formulæ, for instance, the important solutions for simply periodic waves.

Some of these effects have been known and understood from the earliest times, or, more correctly, since the time when William Thomson taught telegraph cable engineers the principles of their business (in its electrical aspects), and, to a great extent, the practice too. They were previously in quite a benighted state, generally speaking, though there were a few, whose names it is needless to mention, who combined enough electrical science with their practical knowledge to have fairly correct ideas about retardation in submarine cables. I do not mention Faraday in this connection, for that great genius had all sorts of original notions, wrong as well as right, and not being a mathematician, could not effectively discriminate, especially as he had so little practical experience with cables.

A complete history of the subject of the rise of Atlantic telegraphy, including the scientific side, written by a man fully and accurately acquainted with the facts, preferably with personal knowledge, and devoid of personal bias, would be of great value and of permanent utility. It will not be very long before no contemporary will be left to do it. Perhaps, on the other hand, it might be more fairly done at second hand. In the meantime, there is a somewhat bulky volume, the Report of the Submarine Cable Committee of 1859, which serves to show the state of knowledge at that date. But it is the history of the march of knowledge in the several preceding years that is important.

The two effects referred to are that resistance and permittance (R and S) act conjointly in producing "retardation," so

Digitized by Google

that both R and S should be reduced to improve the electrical efficiency of a cable. This is embodied in Lord Kelvin's theory of 1855, and gave rise to a rather neat law of the squares, something that practicians could grasp. This law soon became matter of common knowledge amongst cable engineers and electricians generally. But when once grasped they could not let go, and in later times the law has been most grossly abused and misapplied. The fact still remains, however, that R and S are prejudicial. But allowance has to be made for other influences, and it may be very large allowance.

But, very curiously, there has been an exception to the rule. There have not been wanting electricians who, when telephony was extended to circuits containing underground work, supposed that high, not low resistance, was good for telephony. This was giving up the law of the squares with a vengeance. But there was really no warrant for such a conclusion, either theoretical or practical. As this view turned out manifestly wrong by practical failure, it was followed by a precipitate revulsion, the law of the squares being again seized, and grasped more firmly than ever, and against all reason. The fact that R and S are prejudicial does not make the law of the squares. To have that, R and S must be the only controlling electrical factors.

All the other effects are of later recognition, and were mostly discovered, and their laws investigated, and consequences worked out by myself. They completely remodel the subject. The old views remain right, in their proper application, but have a very limited application in general, as in modern telephony particularly. My extended theory opened out a wide field for possible improvements in signalling over long circuits in advance of what could be possible were R and S the only controlling factors, and so far as it goes, modern telephony already goes far beyond the supposed restrictions of the law of the squares.

We should not only consider the effects of varying the four line constants one at a time, but also of combinations. Thus, K may be counteracted by L. The former is beneficial, inasmuch as it lessens the distortion, but it is prejudicial in the attenuation it causes in transit. But if we simultaneously increase L, we counteract the attenuation caused by K; moreover, we still further lessen the distortion. This is corroborative of the preceding remark as to the unreserved benefit due to L. We see, therefore, that [K] and [L] above point the way to salvation, if that be by means of increasing the distance through which signalling can be carried on with a cable of given type as regards R and S. But let it not be forgotten in studying K and L, that R and S themselves might perhaps (in some particular scheme, for example) be reduced as cheaply as K and L could be carried out. Be liberal with the copper, for one thing. Look out for some practical way of insulating the wires which shall not make the permittance be so great as it is at present with gutta-percha or india-rubber. Something of this sort has been done for telephone underground cables, though I do not know the practical merits. But, as regards Atlantic cables, it should be something very good and trustworthy, or the reduced permittance may be bought too dearly.

There has been some difficulty in getting people to grasp the ideas embodied in [K] and [L], especially the latter, of course, on account of its novelty; whilst [K] was already partially recognised by knowing ones, and is capable of very ready explanation. [L] was the trouble. Now, remembering the state of fog that prevailed in the fifties as regards the effects of R and S alone, there is no reason for wonder that more recondite effects, as of L, unaccompanied by prior experience, should not be readily recognised when pointed out, though that was no excuse for burking the matter. [K] and [L], especially the latter, require to be studied to be understood. But if people will not take the trouble to study the matter, how can they expect to understand it? Now I find that there has been too much of an idea that I have merely given some very complicated formula which no fellow can understand, and have made some dogmatic and paradoxical statements about the consequences. But a reference to my "Electrical Papers" will show that I have treated the matter of propagation very fully, in the elementary parts as well as in the advanced, and from many points of view, and that I have not been above pointing the moral by numerical examination of results, whilst at the same time I have been particularly careful in elaborating the theory of the distortionless circuit, on account of its casting so much light upon the subject generally. The notion that has been promulgated, that I cannot make myself understood to physicists, recoils upon its authors with great force. Letting alone the fact that some physicists have understood me, and moreover, the fact that various students have understood me (as I know by my correspondence), there is the very notable fact that the promulgators of the false idea (which must be most discouraging to students) have evidently not taken the trouble to examine my writings to see what my views really are, but have only made acquaintance with a fragment thereof. I have advertised the distortionless circuit so often that I have become ashamed of doing so. Nevertheless, since it is, as I have often pointed out, the royal road to an inner understanding of the subject in general, I do not hesitate now to add some more remarks in connection therewith, and leading up thereto, in attempted elucidation of former work. We should first consider [K] alone, or in conjunction with [R] and [S], and then [L], and finally both [K] and [L].

§ 212. What leakage does is to increase the attenuation of waves in transit, but at the same time to lessen the distortion they suffer. Now there is, by elementary knowledge, no difficulty in seeing why leakage on the line should diminish the strength of the received current, in spite of the fact that the strength of the current sent is increased by the leakage. Ohm's law applied to a simple circuit with a shunt attached will suffice to give the reason so far as one fault is concerned; and the principle is the same for any number of faults, or for distributed leakages.

As regards the lessening of the distortion, that is not quite so elementary. It does not present itself for consideration at all in common telegraph circuits. When, however, a cable is in question, and there is manifest distortion of signals, the influence thereupon of leakage becomes an obvious matter of inquiry. We may do it on the basis of the electrostatic theory. In fact, in his telegraph theory, Lord Kelvin did insert a term in the differential equation to express the effect on the potential of uniform leakage, though it was merely in passing, and I do not think there was any development of the matter in his later papers. The obvious attenuating effect of leakage, and the manifest evils of faults, caused high insulation to be aimed at, and possibly caused the full effect of leakage to be overlooked, and its theory to remain uninvestigated.

Now a cable is a condenser, or leyden, and a very big one too, although its permittance is so widespread that the permittance of a yard or so is very small. The discharge of a condenser against resistance takes time, and so does its charge, and the greater the resistance the greater the time needed. In the extreme, a perfectly insulated charged condenser keeps its charge unchanged, and so does a well-insulated cable, if also insulated at the ends. Even when it is earthed (or grounded, as the Americans say) at both its ends, only the portions close to the end can discharge at once. Away from the ends, the discharge has to take place through resistance, to a varying extent though in different parts, when we regard the long cylindrical condenser as a collection of small condensers side by side in parallel, with all the similar poles joined together by resisting wires. This is how it comes about that the resistance acts conjointly with the permittance in causing "retardation" in cables, so that the electrostatic time-constant is proportional to their product, or RSl^2. It is obvious, then, that we can facilitate the discharge by lessening the resistance to discharge, that is, by leakage in the cable, either distributed or in detached lumps. At the same time the charging is similarly facilitated or expedited.

Now, in making signals from end to end, the operation of charging the cable is necessarily precedent to that of receiving current at the distant end, which, in fact, represents a part of the charge coming out. Therefore, to expedite changes in the charge in the cable, not necessarily or usually complete charges or discharges, results in expediting changes in the current at the distant end. That is, it lessens the distortion at a given working speed, and so expedites the signalling. There is, in

Digitized by Google

; electrostatic theory, no limit to this process, and by suffi ntly reducing the insulation resistance, or, which is the same, reasing the leakance (which is, perhaps, an admissible short ne for leakage conductance), we might signal through the ble as fast as we pleased, were there no other effect produced. is other effect is the extra attenuation. Whilst the possible eed of signalling can be raised apparently *ad lib.*, there is ly an infinitesimal current left to do it with. (Remember at the influence of L is not now in question.) It is important recognise that it is a consequence or natural extension of the l electrostatic theory, without any appeal to self-induction, at you can signal as fast as you like through an Atlantic ble of the present type (with leakage added, of course) simply throwing away most of the current, and utilising the small siduum that manages to survive the ordeal.

Thus, a proper Atlantic cable, suitable for rapid signalling, ould not have high insulation resistance, but the very lowest ssible consistent with getting enough current through to rk with, and other considerations, mechanical and com- ercial, &c. The theory, moreover, is a sufficiently clear one, d does not need elaborate mathematics to make it at least obably accurate, though it may, of course, be desirable to oroughly verify the consequences mathematically.

It is now about 23 years since I came to see, substantially above, the theoretical absurdity of a system of signalling ich deliberately and seemingly of purpose places in the ay the greatest possibly hindrance to the efficient trans- ssion of signals, viz., by the use of the highest insulation ssible, causing them to be regularly strangled, choked, and itilated, to say nothing of their sometimes dying of inanition. But this was mere theory. As a matter of fact, the effect leakage presented itself to me at that time in practice real live cables in a surprisingly different manner. The position between plausible theory and live practice was so aring that it will be instructive to briefly describe it next thus.

(*To be continued.*)

LANDMARKS IN THE HISTORY OF ELECTRO-CHEMISTRY.*

BY W. W. HALDANE GEE, B.SC., F.C.S.

(*Continued from page 501.*)

Dr. William Henry, of Manchester, was also occupied with ectro-chemical experiments. His chemical library was pre- nted to the Owens College by Dr. Charles Henry, F.R.S. o this valuable collection of works reference has been re- atedly made in the preparation of this article.† His "Ex- riments on Carbonated Hydrogen Gas, with a view to deter- ine whether Carbon be a Simple or a Compound Substance," ere published in *Phil. Trans.*, LXXXVII., p. 401, 1797, and mbat the view of Dr. Austin (*Phil. Trans.*, LXXX.), that the ex- ansion of this gas that occurs when electric shocks are passed rough it is due to the decomposition of carbon, and the sub- ance is still to be considered as an elementary substance— at is, as a body, "with the composition of which we are un- quainted, but which may, nevertheless, yield to the labours some future and more successful analyst."

His next series of "Experiments for Decomposing Muriatic cid" appear in *Phil. Trans.*, XC., p. 188, 1800. It was an portant problem to analyse hydrochloric acid, the theory f the nature of acids being regarded as still incomplete nd liable to subversion, until each acid had been resolved nto its individual constituents. Hydrochloric acid gas was confined over mercury in straight glass tubes, furnished at the sealed end with a conductor of gold or platinum. Electric shocks from a frictional apparatus were passed through the gas. The shocks were as strong as could be given without breaking the tube; in some cases, indeed, the apparatus was shattered. After many experiments, in which shocks from 20 to 400 in number were passed, hydrogen and calomel were obtained. In order to avoid the action of the mercury, Mr. Cuthbertson made him a glass tube ground at one end, with the view of receiving two stoppers, each perforated with platinum wire, so that electrical shocks could be passed through any gases with only glass and platinum in contact. With this apparatus he made the following experiment:—

"Experiment 7. In this tube I electrified the muriatic acid gas, and then admitted to it an infusion of litmus. The sudden destruction of its colour evinced the formation of oxygenated muriatic acid. Not the smallest deposit appeared in the tube."

Henry had, in fact, decomposed hydrochloric acid, but in the light of the views then held chlorine was regarded as a compound of hydrochloric acid and oxygen, and Henry supposed its production in this experiment to be owing to the presence of moisture. Biassed by the prevailing theory, he came to the conclusion "that he had not made the smallest progress in decomposing hydrochloric acid." If chlorine contained oxygen it would be expected to yield water if electrified with marsh gas. He accordingly made a mixture of the two gases, to which he gave in different cases shocks to the number of 200 and even 1,000. The result was simply negative.

John Dalton describes in his "New System of Chemical Philosophy," Part II., 1810, many electro-chemical experiments, some of which were made with the assistance of Dr. Henry. Dalton repeatedly used the eudiometer of Volta and the method of analysis of applying repeated electric shocks to ascertain the composition of gases. Many of the experiments had not been previously published, for he was determined to write as little as possible but what he had verified by his own experience. On this account the following electro-chemical references are noteworthy:—

Page 228. Oxygenous gas is not sensibly affected by continually passing electric sparks or shocks through it.

Page 231. Hydrogen gas bears electrification without any change.

Page 234. Azotic gas is not affected by repeated electrification.

Page 285. The experiments of Henry (*Phil. Trans.*, 1800) on the decomposition of fluoric acid are repeated. He electrified a mixture of fluoric acid and hydrogen by a dense stream of sparks for three hours, and noticed a diminution in volume.

Page. 293. A number of experiments on the decomposition of muriatic acid by electric shocks are described.

Page 304. He spent much time in endeavouring to ascertain the composition of oxymuriatic acid.

Pages 321 and 322. Repetition of Priestley's experiment of electrifying nitrous gas and of the Cavendish experiment of synthesis of nitrogen compounds.

Page 374. Pure carbonic oxide is not at all affected by electricity. "I was present when Dr. Henry conducted an experiment in which 35 measures of carbonic oxide received 1,100 small shocks" without decomposition.

Page 382. Carbonic acid is decomposed by electricity into carbonic oxide and oxygen. "I assisted Dr. Henry in an experiment by which 52 measures of carbonic acid were made 95 measures by 750 shocks."

Page 440. When olefiant gas is subjected to electricity either over mercury or water the result is hydrogen, and a quantity of charcoal is deposited. A very careful experiment made in conjunction with Dr. Henry is described.

There are similar experiments relating to other gases, furnishing Dalton with the desired data for the foundations of his great Atomic Theory.

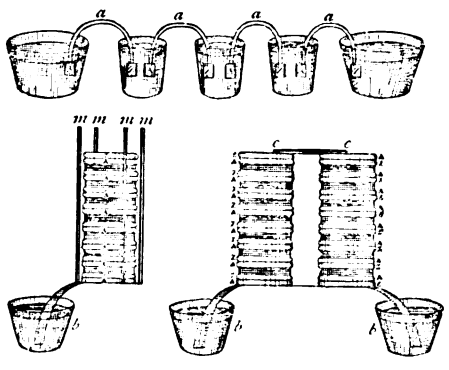
The *Philosophical Transactions* for 1800 contains a letter from Signor Volta, Professor in the University of Pavia. This was the first intimation of the discovery of a new and powerful means of generating electricity, which he thus describes: "I obtained several dozen small round plates or discs of copper, brass, or, better, of silver, about an inch in diameter; for

* The substance of these articles was originally read at a meeting of the wens College Chemical Society. For some help in preparing for publica- on I am indebted to Mr. Vaughan Cornish, M.Sc., F.C.S.

† The three Henrys—Thomas, William, and William Charles—filled an portant place in the History of Science in Manchester. The second one generally considered the most eminent of the three. He published The Elements of Experimental Chemistry," which in 1809 had passed rough eleven editions. *See* Dr. Angus Smith's "A Centenary of Science Manchester," published by the Literary and Philosophical Society of anchester.

Digitized by Google

example, pieces of money, and an equal number of pieces of tin, or, better, of zinc of nearly the same shape and thickness. I say nearly because exactness is not required, and the diameter, as well as the thickness, is arbitrary; it is only necessary to see that the discs are rightly arranged in the form of a column. I prepare next a number of discs of card, or other material capable of imbibing and retaining a liquid. These, which I will call the moistened discs, are rather smaller than the metal plates. One of the metal plates, *e.g.*, of silver, is laid on a moistened disc, and on this is placed a plate of zinc, and on this a moistened disc, followed immediately by silver, which is again succeeded by a moistened disc, and so the apparatus is built up." Fig. 5 shows several arrangements of the apparatus. Twenty pairs were found capable of giving a shock, and many strictly electrical effects were made manifest. When a plate connected with one end of the apparatus was placed on the tongue, and connection was made between the head and the other end of the apparatus, a flash appeared before the eye, and a taste was perceived in the mouth. When metal rods connected with the apparatus were inserted in the ears a peculiar crackling or boiling sound was heard, but Volta did not think it prudent to make the experiment repeatedly. In some of the experiments the *pile* was replaced by a row of glass vessels containing water, or a salt solution, in which were plunged zinc and silver, the arrangement being termed by Volta the *couronne de tasses* (Fig. 4).



FIGS. 4 and 5.—Couronne de Tasses and Volta's Pile.

The publication of Volta's experiments at once excited great interest among philosophers. Anthony Carlisle, a surgeon, with his friend William Nicholson, made experiments described in *Nicholson's Journal* for July, 1800.* Mr. Carlisle constructed one of the galvanic combinations with half-crowns and plates of zinc, with pasteboard soaked in salt water. The pile gave shocks such as Volta had described, and it was ascertained that the effects were without doubt electrical. "Very early in the experiments," says Mr. Nicholson, "the contacts being made sure by placing a drop of water upon the upper plate, I observed a disengagement of gas round the touching wire. The gas, though very minute in quantity, evidently seemed to me to have the smell afforded by hydrogen when the wire of communication was steel. This, with some other facts, led me to propose to break the circuit by the substitution of a tube of water with two wires. On May 2nd we, therefore, inserted a brass wire through each of two corks inserted in a glass tube of half an inch internal diameter. This compound discharger was applied so that the external ends of the wire were in contact with the two poles of the pile." With a pile of 36 half-crowns and zinc plates, a fine stream of minute bubbles immediately began to flow from the point of the lower wire which communicated with the silver, whilst the other wire became tarnished. In two and a-half hours two-thirds of a cubic inch of gas was collected. This was mixed with an equal quantity of common air and exploded. The experimenters from the first believed that water had been decomposed, and that oxygen had attached itself to the upper wire, but it was a matter of great surprise that the oxygen came off at a place two inches distant from the hydrogen. "The decomposition of water and oxidation of metallic wire gave birth to a variety of speculations and projects of experiments." It was found that when wires of platinum were used bubbles came off from both wires. An attempt was made to collect the gases. With a pile of 68 pairs the process was continued for 13 hours. The gases collected were then decanted into separate bottles. On measuring the quantities, which was done by weighing the bottles, it was found that the quantities of water displaced were, respectively, 72 grains on the zinc side, and 142 grains on the silver side, or nearly in the ratio of one to two.

A pile of 100 half-crowns and a like number of zinc plates was next employed. With this pile Mr. Nicholson observed a chemical phenomenon which appeared to him the most remarkable he had yet observed. When copper wires were used, and dilute hydrochloric acid instead of water was placed in the tube, there was a deposit of copper which increased so as to form a metallic vegetation.

Cruickshank,* of Woolwich, repeated and extended these experiments; using a pile of 100 pairs, he decomposed lead acetate (sugar of lead), copper sulphate, and silver nitrate. With the last the metal shot out into fine needles, like crystals, articulated as in the *arbor Dianæ*. He also drew attention to the fact that alkalies always were liberated at the negative and acids at the positive pole. The name of Cruickshank is chiefly remembered for the battery he invented, consisting of zinc and copper plates inserted in a trough.

As the galvanic apparatus became better known it excited much interest, and Volta, its discoverer, was highly eulogised. The National Institute of France presented him with a gold medal, and the French Government bestowed on him 6,000 francs as a mark of esteem. Pile building became a fashionable pastime, and the changes were rung on the metals and liquids employed. Thus Colonel Haldane set himself the task of comparing the effects obtainable with zinc, gold, silver, iron, copper, lead, tin, and mercury, trying the effect of each pair of metals except, indeed, of gold with mercury, and of silver with mercury, a restriction only reasonable considering that the silver was represented by 20 to 200 half-crowns, and the gold by 40 to 56 guineas. The intense interest excited by the subject of galvanism is thus described in the introduction to the *Recherches Physico-Chimiques* of Gay-Lussac and Thenard: "What an impulse has been given to research by the discovery of the pile! What enthusiasm it has excited! Everyone is making piles of every conceivable variety of form. Societies are formed with the sole object of making observations on them, and everybody wants to understand them."†

(To be concluded.)

THE TRANSMISSION OF ELECTRIC SIGNALS THROUGH SPACE.

Nearly a year ago we commented on a description in *The Times* of some experiments made by Mr. Preece on telegraphy without wires. The details then given were very vague, and some suggestion was made about the use of Hertzian oscillations. We observed that the effects might be explained by

* "Account of the new electrical or galvanic apparatus of Volta and experiments performed with the same.—W.N."

* *Nicholson's Journal*, July, 1800.

† Becquerel ("Traité Experimental de l'Électricité," T. I., p. 108) makes the following significant remarks:—"Une société galvanique s'organisa à Paris vers le commencement de l'an XI. Elle était composée de médecins et de physiciens, qui devaient s'occuper spécialment et exclusivement de tout ce qui avait rapport à la découverte de Galvani. Cette société s'organisa, forma des commissions, fit même des expériences, mais il n'en est résulté aucune découverte nouvelle. Il en arrive toujours ainsi dans les réunions composées d'un grand nombre de savants; on discute, puis l'on se sépare. Les découvertes sont ordinairement l'œuvre d'un seul non de plusieurs."

Digitized by Google

urrents returning through the earth rather than by induction, nd ventured to hope that when the time came for Mr. Preece o describe his experiments with his usual lucidity, the confusion nd ambiguity of this preliminary bit of newspaper science ould matter little. The time has come, but we regret that ır wish has been by no means gratified. A Paper has been ad at Chicago by the author of these experiments, but though e have given it most careful attention, we must confess that ıe theoretical conclusions as well as the description of the ıperiments are of an indefinite character.

After a brief and introductory summary of earlier experiments, ection 1 begins as follows :—"When a linear conductor dips ; each end into the earth, with which it makes a good con- ection, and voltage is impressed upon it by any means, the sulting return current would probably flow through the earth a straight line between these two points if the conduction of ıe earth were perfect ; but as the earth, *per se*, is a very poor nductor indeed (and probably is a conductor only because it moist), lines of current flow spread about symmetrically in a ay that recalls the figure of a magnetic field. These diffused turn earth-conduction currents are evident at great dis- nces."

A diagram follows, showing the paths of the return currents. ssuming that the earth is homogeneous, and that the distor- ɔn of earth currents by regions of good or bad conductivity e neglected, we fail to see how a change in the conductivity the earth can alter the lines of current flow in the slightest gree. Lines of current flow do not depend upon the disin- nation of the current to a high current density ; the current es not spread out in curved paths because there is no room it in a narrow one, but because of the mutual repulsion. r. Preece's views are, perhaps, to be accounted for in practice the want of homogeneity of the earth. In a poorly conduct- g soil the currents, finding a difficulty in returning, seek ths of lower resistance, even though they may be obliged to ɛe circuitous routes. In water the currents would follow the rmal paths. In sea-water Mr. Preece finds that with primary rrents of 15 amperes, effects have been traced to one-third of nile. In the absence of any information as to the distance tween the points of entry and exit this tells us nothing.

"It is very necessary," says the author, "to be able to dis- ıguish or separate these earth currents from currents due to luction, for they are very apt to give false effects and to lead erroneous conclusions. This is easily done, if the instru- ɛnt be sensitive enough, by making the primary current con- ıuous when the earth current also becomes continuous, while luction currents are momentary, and are observed only ring the rapid rise or fall of the inducing cause."

This introduction is followed by some elementary considera- ɔns of electrostatic induction, allusion to Faraday's idea of e nature of electric current, and to the hypothesis of Max- ll and Poynting. "The truth," Mr. Preece remarks with ution, "lies probably in a combination of each view." A ries of experiments of a very simple character, but conducted a very large scale, are then described. "Conductors of pper wire, insulated with gutta-percha, were formed into ıarter mile squares, and laid on a level plain at a distance a quarter of a mile apart. Arrangements were made r sending vibratory or alternating currents, which would broken into Morse signals by means of a telegraph y. Telephones were used as receivers." Signals could, of urse, be transmitted. So far, the experiment is plain enough, t we fail to make much of the next paragraph. "Next, order to ascertain to what extent, if any, electrostatic effects ere observable, one pole of the battery used was put to earth, d the further end of each square was disconnected. Now, this arrangement, the mean electric force of one square was ubled, as compared with the former experiment, where the cuit was completed ; but no effect was observed in the second ıare, either in the receiving telephone or with the reflecting lvanometer." If an alternator were used instead of a battery, d if "mean electric force" is intended for average difference potential between the squares the proof would be satis- tory.

Several cases of induction between straight wires and ıares are considered, some of them being of so obvious a character as to be hardly worth recording. The rela- tions between the length and distance of the wires are con- sidered ; but the wires of "finite length" appear to have been put to earth at each end. It is confessed that "the reverse effect of the return circuit through the earth" ought to be allowed for ; but after this admission has been made, earth currents are practically ignored in the remainder of the Paper. Some of the formulæ are inexplicable, unless they are intended for very rough approximations of extreme values. With two squares, for example, of equal dimensions lying in the same plane, the inductive effect is said to vary directly as the length of one side, and inversely as the square root of their distance apart, when this distance is short compared with the length of the side ; but as soon as the distance exceeds half the length, Mr. Preece informs us that it suddenly jumps to another value, viz., directly as the length and inversely as the distance. Of course, when the distance is "very great the effect would diminish, and ultimately disappear, owing to the opposing current in the back of the square having practically the same influence as that in the front."

The experiments between Flatholm and the coast of South Wales ought to have been of great interest, but after reading them with care we cannot think that the whole of the ob- served effects were due to induction as Mr. Preece suggests. At Lavernock Point, near Cardiff, two thick copper wires were suspended on poles for a distance of 1,267 yards, the ends were earthed, and an alternator driven by a 2-H.P. steam engine sent a current of any desirable strength up to a maximum of 15 amperes at 192 ∾ through the circuit. The current was broken up into Morse signals by a suitable key. On Flatholm, 3·1 miles away, an insulated wire was laid for a length of 600 yards ; the ends, we suppose, were earthed, and the circuit included a telephone. From the illustrations which appear in the New York electrical journals it seems that the wire on the main land is inclined at an angle of about 60deg. to the direction of Flatholm. There was no difficulty in communicating between the two circuits. At Steepholm, an island 5·35 distant, and in a direction at right angles to the "primary circuit," the signals were percep- tible, but conversation was impossible. A small steam launch was used to drag half a mile of gutta-percha-covered wire up and down between the primary circuit and the islands. The end was attached to a buoy, but, we presume, was not insulated, but was left bare at the buoy end and earthed to the tug through a telephone. As long as the wire was near the sur- face signals were heard, but when it was allowed to sink in deep water no effect was perceptible. In this way, says Mr. Preece, it was possible to trace without any difficulty the region where the lines of current flow ceased to be perceptible as earth currents, and where they commenced to be solely due to electro- magnetic waves. "The total absence of sound in the sub- merged cable," he writes, "rather surprised me, and it leads to the conclusion, either that the electromagnetic waves of energy are dissipated in the sea-water, which is a conductor, or else, that they are reflected away from the surface of the water like rays of light." This experiment is interesting, but the expla- nation is not convincing. The currents set up by the electro- magnetic waves would be opposed to the earth currents, which Mr. Preece ignores. While at the surface the wire would be fully exposed to induction effects, but as it sank it would more and more tend to pick up the earth currents, and the two effects would neutralise each other. The general practical conclusion arrived at in the Paper is that signalling would be possible be- tween two wires, each 10 miles long and 10 miles apart, no mention being made of the necessary current. Mr. Preece concludes by pointing out that "as these waves are transmitted by the ether they are independent of day or night, of fog, or snow, or rain, and, therefore, if by any means a lighthouse can flash its indi- cating signals by electromagnetic disturbances through space, ships could find out their positions in spite of darkness and of weather. Fog would lose one of its terrors, and electricity becomes a great life-saving agency." It is not difficult to throw out such a suggestion. We did so, in fact, in a Note some two and a-half years ago. But it does not seem that these elaborate experiments make any appreciable advance towards its realisation.

It is of practical interest, and possibly, of practical importance, to transmit signals as Mr. Preece has done over a distance of several miles. Having done this, it would be of scientific interest to learn whether the signals were due to earth currents or to electromagnetic radiation. Evidence to show the nature of the signals, and for which we have been waiting for nearly a twelvemonth, is not to be found in Mr. Preece's Paper. We have assumed that the ends of the "secondary" wires were earthed, if they were sealed up and insulated, a telephone being used instead of the spark-gap of a Hertz resonator, our objections fall to the ground. It would be easy to prove the non-existence of earth currents. In one place Mr. Preece admits this, but on the whole he ignores them. A continuous current in the primary, and an interruptor with a telephone in the secondary would give signals due only to earth currents, exactly as the ringing of electric bells near the City and South London Railway. The effects would, no doubt, be improved by immersing earth plates in the sea instead of burying them on land. Luminiferous ether, and all that sort of thing, would unfortunately be eliminated. To secure purely inductive effects would be more difficult, and the advantage of using them is not very evident. A telephone instead of a spark-gap on a straight insulated line does not seem very promising, and the only way would be to use the pairs of squares referred to in the earlier part of the Paper.

But Mr. Preece seemed to make rather too modest a claim when, in the course of a brief discussion after the reading of his Paper at Chicago, he said that he would not expect a ship to get a communication from a greater distance than the length of a ship. This is, indeed, sticking to the ether theory, for we thought it had already been accomplished by earth currents.

Regarding Flatholm as a ship 600 yards long, it has been found possible to communicate with it from a distance of about nine times its own length, this distance being about four and a-quarter times the length of the primary circuit, or five times its projected length. Mr. Preece, we are glad to learn, intends to investigate the flow of earth currents. In doing so we hope that he will be enabled both to develop these interesting and perhaps important methods of signalling without wires, and add to our knowledge of the behaviour of the earth as a conductor. The old idea of the earth as a vast reservoir or sink or body of zero potential served excellently for early telegraphic work, but its use as a return conductor for purposes of electric traction compels us to acknowledge the existence of return currents, and any light that can be thrown upon them will be of undoubted practical value.

INTERNATIONAL ELECTRICAL CONGRESS AT CHICAGO.

A full account of this Congress, together with several of the Papers in full, abstracts of others, and reports of many discussions, appeared in the *Electrical World* of New York for September 2nd. From this account we have prepared the following abstract:—

The Electrical Congress at Chicago was "called to order" on August 21st by Prof. Elisha Gray, who delivered an address of welcome. An organisation committee was appointed to elect officers, and during its sitting Prof. Ayrton gave a short address on American electrical engineering and on the Exhibition from a stranger's point of view. The display of electric lighting and tramways filled him with admiration, and he felt pleased to know that they had no Board of Trade to control their affairs, but the mode of constructing their tramways, the telephone, telegraph, and high-pressure electric light wires jumbled up on the same posts, sometimes with the insulation a little defective, reconciled him to the dominion of Whitehall; and he took comfort in the thought that high-pressure transformers in his own country were not stuck like flies on the house walls. Looking at the Exhibition even from a purely American standpoint, he did not think that the exhibits inside quite did justice to the country. There was no model or plan of the Niagara scheme, while at Frankfort they really saw the thing done. At Frankfort it was what was inside the electrical building that dazzled his mind; at Jackson Park it was what was outside the Electricity Building that rivetted his attention. Prof. von Helmholtz was elected President, and made a short speech, being followed by Prof. Gray, Mr. Preece, and Prof. Mascart. The Congress then adjourned until the next day.

On Tuesday, 22nd, Section A, devoted to pure theory, met with Prof. Rowland as Chairman, but no blackboard having been provided, the meeting adjourned.

On Wednesday, 23rd, Prof. A. Macfarlane, of the University of Texas, read a Paper on "The Analytical Treatment of Alternating Currents," in which he described what was meant by natural analysis, and criticised the graphical method of Bedell and Crehore as not being applicable to complex cases. The purpose of the Paper was to show that not only the applications, but also the fundamental principles, are obtained by plane algebra, which he defined as the algebra of complex quantities. The next Paper was by Mr. C. P. Steinmetz on "Complex Quantities and their Application in Electrical Engineering." This Paper contained a novel method of the treatment of alternating currents, which simplified methods involving complex quantities, by supplanting all periodic functions and trigonometric functions with constant quantities of simple algebraic expressions. The device is to introduce the letter j in the expression of the sine curve, at first simply as a distinguishing index without mathematical meaning, and afterward as $j = \sqrt{-1}$. Complex quantities can then be treated as simple quantities, and only a knowledge of algebra is necessary to handle them.

The next Paper was by Drs. Bedell and Crehore on "The General Discussion of the Current Flow in Two Mutually-Related Circuits Containing Capacity." This Paper was a continuation of one presented at the general meeting of the American Institution of Electrical Engineers at Chicago, June 7, 1892, in which the authors considered the problem of finding the current which flows in a single circuit having resistance, self-induction, and capacity in series, with a low frequency and low magnetisation, and when no iron is present. Throughout the Paper, the reading of which was continued on the next day, the coefficients of self-induction were assumed as constant, not taking into consideration, therefore, the changes in self-induction, magnetic leakage, or, indeed, the presence of iron.

On Tuesday, Dr. Johann Sahulka, delegate, Technische Hochschule Vienna, next read a Paper on "The explanation of the Ferranti Phenomenon," in which he endeavoured to show that the "Ferranti Phenomenon" was based upon the magnetic leakage of the transformer.

The Papers for the last day were: "Measuring the Power of Polyphase Currents," by A. Blondel; and "The Extended Use of the Name Resistance in Alternating Current Problems," by Prof. W. E. Ayrton, but owing to the absence of the authors they were "read by title." The section was adjourned *sine die*.

Section B dealt with Theory and Practice. Prof. Cross was elected Chairman. The first Paper was that by Mr. Preece on "The Transmission of Electrical Signals Through Space."

In the discussion, Mr. Lockwood described somewhat similar experiments made many years ago by Morse and others. Mr. A. W. Heaviside described an interesting case, in which communication was found possible from an underground mine to the surface, without any direct connection. Mr. Lemp suggested that the area of loop in electromagnetic induction signalling might be of importance.

The second Paper was on "Ocean Telephony," by Prof. Silvanus P. Thompson. The Paper was greatly appreciated by the members, as was shown by prolonged applause; the discussion was postponed until the next day.

A large portion of the second day was devoted to the postponed discussion of Dr. Thompson's Paper. Prof. Jamieson estimated that the cost of such a cable would be about three times as great as that of the one in ordinary use at the present time, and that it would be difficult to locate faults. Mr. Kennelly called attention to the fact that it might be balanced for one particular frequency, and for one only, but that with the distortionless circuit proposed by Mr. Lodge the line might be balanced for all frequencies. Mr. Alex. Siemens, Mr. A. W. Heaviside Prof. Cross, and others also contributed

Digitized by Google

me interesting remarks to the discussion; in general the ea was favourably commented upon, but it was shown that fficulties arose, which, however, were probably not insur-ountable.

The next Paper was that of Dr. Lindeck on "The Best aterials for *Resistance* Coils." It was a very careful summary data collected from various sources, principally from the eichsanstalt. A Paper by Mr. Kennelly on "The Temperature efficient of Copper" was then read. In Prof. Thomas's aper on "Photometric Measurements," which followed, spoke of the apparent errors which have been noticed the law of the inverse squares, and showed that one source error was due to the reflection from the inside of the glass ylindrical chimney or spherical bulb of the lights.

On the third day Prof. Carhart read a Paper on "Electrostatic oltmeters." These instruments combined the electrometer rinciple with that of the torsion head, and were, therefore, zero eading instruments. The next Paper was that of Prof. Tebster on "A Method of Governing an Electric Motor for hronographic Purposes." He uses a tuning fork to obtain bsolutely constant pulsations of the current, the motor being synchronous one. Prof. Ewing's Paper on "Iron for Trans-rmers" was read by the Secretary, Prof. Ewing not being resent. In general he laid great stress on hysteresis losses nd less on high permeability. Prof. Jamieson read a Paper n "London Electrical Engineering Laboratories," Dr. Bedell on "Transformer Diagrams Experimentally Determined," and Mr. ennelly on "An Improved Instrument for Measuring Mag-etic Reluctance."

The sitting of the fourth day, which was devoted entirely to he subject of arc lights, was opened with Prof. Ayrton's Paper n "The Variation of the Potential Difference of the Arc ith Current, Size of Carbons and Distance Apart." In it he ave the results of a very complete set of tests made with c lamps. M. Violle read a Paper in French on the bject of "Light and Heat of the Arc." The next Paper, at of Prof. S. P. Thompson, on "The Swinburne-hompson Unit of Light," was read by title at the sug-estion of the author. In Prof. B. F. Thomas's Paper on "The eriodic Variation of the Candle-Power of Alternating Arc ights," which followed, he gave the results of measurements the arc at successive points of the current wave, showing me interesting features, one of which was that the intensity the light followed instantly any changes in the current. rof. Carhart read his Paper on "The Maximum Efficiency of rc Lamps with Constant Number of Watts" in abstract only, the matter was included, to some extent, at least, in Prof. yrton's exhaustive Paper. The meeting closed with the read-g by title of two Papers in French by M. Blondel, one on New Researches with the Alternating Current Arc," another n "The Constant Current Arc and its Employment as a tandard of Light," and the last by Prof. Rowland on "The ource and Effects of Harmonics."

Section C, of which Prof. Houston was elected chairman, was evoted to "Pure Practice." On Tuesday Prof. Houston made brief introductory address, in which he called attention to the ct that while the Congress had been divided into three sections, o difference in reality existed between the various parts. The reat advantage would come from the intercourse of the repre-entative men of different nationalities, and it might seem as if would have been better if no division or a division along dif-rent lines had been made. Mr. F. Shulze-Berge read a Paper n "Rotary Mercurial Air-Pumps." Mr. Shulze-Berge and his rother have devised a form of pump which consists of a ollow ring of steel, about one metre in diameter. This revolves bout an axis, one end terminating in a stuffing box. The ollow ring is partly filled with mercury, and connected by a ree-way cock and tube to the axis.

On the second day Prof. D. C. Jackson read a Paper on Underground Electric Construction in the United States." rof. Jackson described four kinds of subways now more or ss in general use in the United States, viz., those constructed : (1) Iron; (2) sheet iron laid in cement; (3) clay or terra-tta; and (4) wood. Mr. F. Sahulka read a Paper on "The arious Uses of the Electrostatic Voltmeter." Prof. L. B. larks read a Paper on "The New Incandescent Arc Light."

The meeting on the third day was opened by a Paper "On Direct-Current Dynamos of Very High Pontential," by Prof. F. B. Crocker, of Columbia College. After stating that by very high potentials he meant potentials from 5,000 to 11,000 volts, Prof. Crocker pointed out the essential features of such construction, and proceeded to a description of two machines built by him, one of 1 H.P., with a potential of 5,000 volts and only 32 commutator bars, and the other of about 11,000 volts, at 1,800 revolutions per minute and 108 commutator bars. The current in this machine was, of course, small, not exceeding 4 amperes.

Dr. Louis Duncan, of John Hopkins University, was then asked to open the discussion on "Multiphase Motors and the Transmission of Power." He explained why the alternating-current motor, leaving out of consideration self-induction, had a higher efficiency than the continuous-current machine on account of the better distribution of the E.M.F. Starting an alternating-current motor was the great difficulty. This could be done, of course, but often with the consumption of a large amount of energy, and at the expense of everything else on the same line. Mr. M. F. C. Hasson, in giving the history of the transmission of power by electricity in California, said that so far it had been a failure, at least from the standpoint of the investor. Dr. Louis Bell considered the three methods of transmission: (*a*) By high potential currents; (*b*) by single-phase alternating currents; (*c*) by polyphase alternating currents. Prof. S. P. Thompson, at the request of M. Thury, mentioned a number of direct-current high potential plants in Europe where large horse-powers were very successfully distributed. Prof. Thompson gave further instances in which direct current distribution at high potential had been tried. Prof. Geo. Forbes, gave his views of the advantages of the various systems. He favoured the two phase system with two independent circuits, and had recommended this for the plant at Niagara. Mr. C. P. Steinmetz closed the discussion, saying that justice compelled him to defend the direct current, although he was most interested in alternating-current work. He thought the single-phase system was the system of the future.

On the fourth day Dr. C. Pollak then made some remarks concerning the device for converting alternating into continuous currents. Prof. George Forbes then continued the discussion upon multiphase motors and the transmission of power, which was opened by Dr. Louis Duncan at the session of Thursday. Prof. Forbes stated that all the great firms of the world had been asked for plans for the transmission of power from Niagara Falls to Buffalo, and that the bids for continuous-current system were much larger than any of the others. They had decided upon the same system of transmission for short and long distances. He thought a single device for transforming alternating to continuous currents full of great possibilities for the future, and that alternating-current arc lamps might come into general use before many years. He then briefly touched upon the question of the step-up transformer. Prof. H. A. Rowland differed with Prof. Forbes in that he favoured the use of step-up transformers instead of very high potential dynamos. He then took up the question of frequency, discussing its higher and lower limits.

On the afternoon of Friday, 25th, all the sections met as a General Congress. On the platform were the official representatives of the various Governments who had been in conference in the Chamber of Delegates. The report of that body on electrical units was read, and votes of thanks and speeches from Prof. von Helmholtz, M. Mascart, Mr. Preece, and Prof. Gray brought the Congress to a close.

Paper Belts.—According to the Boston *Commercial Gazette*, manufacturers will find that paper belting will replace that made from leather with advantage. Rubber and cotton have already been tried as substitutes for this purpose, but a belt made of paper is found superior to these, as it becomes covered with a hard shining surface in working, which makes the belt very durable. In making the belts, links made from strong paper pulp are used, and after working for some time, the coating of the belt next to the pulley becomes so hard that it can only be cut with the chisel.

STEEL-PLATE PORTRAITS

Of Willoughby Smith; W. H. Preece, F.R.S. (President of the Institution of Electrical Engineers); Michael Faraday; Sir John Pender, G.C.M.G., M.P.; Sir William Thomson, F.R.S. (Lord Kelvin); C. H. B. Paley, C.B.; Dr. John Hopkinson, F.R.S.; Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S.; Prof. von Helmholtz; Prof. W. E. Ayrton; Lord Rayleigh, F.R.S.; Cyrus W. Field; Werner von Siemens; and Sir James Anderson, have been issued as Supplements to "THE ELECTRICIAN."

Copies of these admirably-executed Steel Engravings can be supplied price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price 4s. 6d., carriage paid (U.K.).

THE CHICAGO CONGRESS.

The Electrical Congress at Chicago appears to have been the only feature of the Chicago Exhibition that has passed off without a hitch, and, judging from the reports that have reached us up to the present, it may be accounted a success. Elsewhere in our present issue will be found an abstract of a report of the proceedings, and the text of the report on electrical units. In an early number we hope to give our readers a summary of the Congress from the pen of one who was present. We recently reviewed the constitution and the results of the former international electrical congresses. At most of these, and we may reckon among them the conference at Edinburgh during the last meeting of the British Association, some real progress was made and important resolutions were carried. Some of these resolutions, such as that naming the "quadrant," have been superseded, and others, such as that dealing with the 106 centimetre ohm, were only of a temporary character. No important steps were expected of the International Congress, for its unfortunate association with an International Exhibition placed it at a considerable disadvantage. It succeeded, however, in attracting a sufficient number of good men to make a show on the platform, and by carefully avoiding controversial points, and solemnly adopting a set of units which, Congress or no Congress, have been accepted by the civilised world, it saved itself from being ridiculous. The question of a unit of light, as must be apparent to all those who have paid attention to it, is quite unripe for decision. The arc standard, on which several experimenters are at work, even though it may turn out to be a practical and trustworthy standard, is in no sense a unit. The other matter which the Congress put aside, the system of symbols and notation suggested by M. HOSPITALIER, may or

Digitized by Google

may not be ready for universal use, but the Congress was far from strong enough to carry it, even if the system were beyond criticism. To attempt to increase the unit of current tenfold, making a new ampere equal to the C.G.S. unit of current, was quite out of the question at a gathering of this kind. The adoption of the henry, and the public and international ratification of the labours of the Board of Trade Electrical Standards Committee and of the Edinburgh Conference will, however, remain a justification for the holding of the Chicago Congress.

We have recently remarked that the reading and discussion of Papers has no obvious connection with a Congress which is summoned to consider and pass resolutions of International importance. The only advantage of such a combination is that by intercourse of representative men of different nationalities, useful discussion may be elicited. The discussions, judging by the reports in the American electrical journals, did not, however, rise above the desultory conversations of a sectional meeting of the British Association. A discussion pure and simple, with no Paper as a text, might yield most valuable results if carefully managed. The subject ought to be announced months beforehand, the speeches arranged as for an important debate. An attempt was made in this direction by a discussion on "Multiphase Motors and Transmission of Power." Nothing new was disclosed, but there were as many views as speakers.

Turning from the discussions which can alone be the excuse for communicating Papers to such a gathering, to the Papers themselves, we find that some were only "read by title," and others were not printed; they appear, on the whole, to have been of the usual British Association character. The most important communications seem to have been that of Prof. S. P. Thompson on ocean telephony, of Prof. Ayrton on arc lamps, and of Mr. Preece on telegraphy without wires. The first of these we have already published; the second is, we understand, very long and elaborate, but we hope to give an abstract of it; the third is discussed elsewhere in our present issue. Prof. Marks's enclosed arc light was described in our columns last week. The Papers by Dr. Lindeck, Prof. Ewing, and Prof. Rowland are sure to be worth studying, but descriptions of a chronograph device, and of a mercurial pump, seem to be quite out of place at an international congress. The novelty of Mr. Steinmetz's mathematical device is not very apparent, but if his Paper contains anything which will really simplify complex expressions it will be welcome. The mathematics of Drs. Bedell and Crehore promised at one time to be very attractive, employing as they did graphical methods and appearing to deal with practical problems, but their last effort is very disappointing; few electricians and fewer electrical engineers will trouble themselves about analytical work in which the presence of iron is ignored. To one Paper, which has appeared in the *Electrical World* of New York, we record our strong objection elsewhere. The holiday nature of this part of the Congress is apparent enough in the comparative unimportance of some of the Papers. If strict rules had been made for the reception of Papers a month or so before the opening, for their examination by a small and strong committee, and for the printing and distribution of the accepted Papers before reading, it would have been unnecessary to divide the Congress into three sections. But what holiday meeting is strong enough to attempt this, and outside two or three scientific societies, where is it done? We hope that our special account of the Congress will disclose some new features of interest, and that the Chicago Congress of 1893 may prove to have achieved something more stirring than a mere ratification of previous conclusions.

REVIEWS.

Scientific and Technical Papers of Werner von Siemens. Vol. I., Scientific Papers and Addresses. Translated from the Second German Edition. (London: John Murray.)

The great strides that have been made within the last thirty years or so in the science of electricity and in its applications, cannot be adequately realised by the student of to-day unless he has made himself acquainted with the difficulties, investigations, and theories of the founders of modern electrical science. An assured, but certainly a somewhat laborious way of attaining this knowledge is to read the collected Papers of men like Werner Siemens. These Papers, while they cannot compare from the point of view of lucid exposition and unity of purpose with the classic experimental researches of Faraday, present, nevertheless, numerous points of practical and scientific interest, and cover a wide field, ranging from details of telegraph construction and operation to investigations on electric resistance, static induction, and theories of solar and meteorological phenomena. In a Paper published in Poggendorff's Annalen, in 1850, Werner Siemens has much to say about the advantages of the then novel bell-shaped telegraph insulators, and about the difficulties caused by lightning and static charges on long telegraph lines; "hardly a summer passes with a long overhead line that the lightning does not strike it, damaging the instruments, and partly destroying the line." In the same year, a long memoir, presented to the Académie des Sciences described certain curious phenomena observed on long underground lines, reasons being given for thinking they were due to electrostatic induction and not to "secondary polarities" developed in the wires. Earth currents are also alluded to, and their generation attributed to variations in the magnetism of the earth. In 1857 Werner Siemens published a Paper in Poggendorff's Annalen on "Electrostatic Induction and Retardation of the Current in Cores." This contribution, which occupies no less than fifty pages of the present volume, is largely devoted to accounts of experiments made with a view to test Faraday's "contiguous particle" theory of electrostatic induction, and contains a passing reference to the electrolysis of glass. The conclusion drawn from numerous experiments is "that it is very likely that the seat of the electricity is removed from the conductors to the non-conductors surrounding them, and may be defined as an electrical polarisation of the molecules of the latter. The conductors would then only be conceived as polarised spaces in an electrically polarised medium, with the property of being able to carry over the polarisation in their medium from one point of their surface to another. If the specific inductive capacity of the conductor may be assumed as very great compared with that of the non-conductor and proportional to its conductivity, its induction maximum, on the other hand, as infinitely small, then all conditions for the explanation of the phenomena of the electric current and also its attraction and repulsion appear to be fulfilled." In 1875, Werner Siemens endeavoured to measure "the velocity of transmission of electricity in suspended wires," and obtained the figure of 256,600 kilometres a second. In 1880, the experiments of Matthiessen and Auerbach being contradictory on the important point of the increase of the conductivity of carbon with rise of temperature, Werner Siemens set to work to settle the question, and found that up to 900° C. the resistance of carbon continued to decrease, the conflicting results obtained by other observers being attributed entirely to defective end connections. We may conclude our notice with the following lively account of a scientific investigation carried out by Werner Siemens and a party of friends on the summit of the Cheops pyramid during the blowing of the "chamsins." Having reason to suspect electrification of the atmosphere, the party proceeded to investigate the matter. "After the Arabs had watched our proceedings for a time with wonder, they came to the conclusion that we were engaged in sorcery, and requested us to leave the pyramid. As their remarks, when interpreted to us, were without effect, they wanted to use the power of the

Digitized by Google

strongest to remove us from the top by violence. I withdrew to the highest point and fully charged my strengthened flask, when the Arab leader caught hold of my hand and tried to drag me away from the position I had attained; at this critical moment I approached the top of my flask to within striking distance of the tip of his nose, which might be about 10mm. The action of the discharge exceeded my utmost expectation. The son of the desert, whose nerves had never before received such a shock, fell on the ground as though struck by lightning, rushed away with a loud howl, and vanished with a great spring from our vicinity, followed by the whole of his comrades."

Griffin's Electrical Price-Book. Edited by H. J. Dowsing. (London: Charles Griffin and Co. 1893.)

A book breaking fresh ground is not to be too critically judged, especially when it is one of a class which must necessarily pass through continual revision, if not regular annual editions. This price-book, edited by Mr. Dowsing, has many of the good points of Laxton and other well-known publications, but with these as guides something more might have been expected. The discussion of such matters as "Statutory Powers," "Selection of a Site for a Central Station," "Notes on Foundations for Machinery," "Digest of Board of Trade Regulations," &c., would be all very well in a general handbook, but they must be treated at sufficient length to allow some really useful information to be given. As introductions to different sections a single paragraph should be sufficient, a page or two of smattering is useless, except to smatterers. One of the very first lists is an example of the mechanical copying of a very old-fashioned price list of steam-engines—old-fashioned, not because the quotations are out of date, but because nominal horse-power is given without a hint of the brake, or even of the indicated horse-power. The price list of boilers described only by nominal horse-power is still more absurd. For the sake of uniformity the sizes of lubricators which are dotted about among these lists should have been given in nominal horse-power instead of in pints. Only three makes of steam engines are given. Gas engines are better done, but the cautious "approximate indicated horse-power" is in most cases given instead of brake horse-power. This is, of course, the editor's misfortune, not his fault. Messrs. Crompton and Co. naturally occupy the larger portion of the space devoted to dynamos, as well as of the other sections dealing with their manufactures. The "Westminster" and "Silvertown" dynamos are not quoted, nor are any Continental makes included.

Having recently searched the lists of most of the leading firms in vain for a 2 H.P. alternator, we were interested to find under "Dynamos-Alternating Current" a list of "'Heaton' Dynamos," by C. A. Parsons and Co., beginning with 1·2 kilowatts at 1,250 revolutions. But on closer examination, the prices for "machine shunt or compound," "spare commutator," and so on, suggests that these are continuous, current machines. The section on storage batteries is fairly complete, but the Drake and Gorham "D. P." accumulators are not mentioned. A considerable number of minor errors will, of course, disappear in future editions, such as the inclusion of Crompton's potentiometer and sundry other instruments under the manufactures of Goolden and Co.

Several makers of insulated cables and well-known arc lamps are omitted, and under the heading of "Warming and Cooking, &c.," no mention is made of the General Electric Company's goods. The expression electromotive force we have heard of, but rarely use; what is "Electromotive Power"? Nothing more than electrical transmission of power. Not a single alternate-current motor is offered—again no fault of the editor. After some table of statistics, a "specimen" report by Mr. Preece on the lighting of "A Provincial Town," and another, with estimates by Mr. Crompton, are given. Some very poor sample specifications follow, and a few very vague estimates, wiring and fire insurance rules, a few memoranda and tables, and a rather careless index, conclude this very well-intentioned, but rather disappointing book. The compilation of such a work is necessarily very laborious, and the first issue naturally fails to be perfect. We have said enough to show that with all its short comings it contains a great deal of information which can only be obtained by searching through files of catalogues—a most tiresome proceeding; and it may be expected that future editions will prove to be most useful in several different branches of the electrical trade and profession.

Lightning Express Railway Service. By F. B. Behr.

Our readers who are interested in the problem of high-speed railway service, which has recently been discussed in our columns (see *The Electrician*, Vol. XXXI., p. 475), will find a considerable amount of food for reflection in the pamphlet before us. Mr. Behr attacks the problem in a manner which clearly shows that he is fully cognisant of the difficulties which envelop it; and, though we are not quite prepared to follow him to the full extent in regard to the system he advocates, we are quite in agreement with him where he shows the impracticability of adopting the existing railway systems to any very much more rapid service. In the first section of his book the author answers negatively the question—Are the ordinary existing lines suitable for speeds of 120 to 150 miles an hour? In the second section the general conditions of construction for high-speed service are discussed, in regard to the track, the rolling stock, and the working arrangements. The remainder of the work is devoted to an elaborate defence of the Lartigue single-rail system as the "only one satisfying all the requirements." This system has recently been adopted for a railway from Feurs to Panissières, in France, which is in process of construction; but the only instance, as far as we are aware, of an actual, extended trial of the system was on a length of 9½ miles of line between Listowel and Ballybunnion, in Ireland. In matters of engineering pioneer work, it has been proved over and over again that the only true criterion is actual practice. A scheme may appear excellent on paper; it may satisfy every engineering equation which tends to place an obstacle in the way of success. But it does not follow that the scheme will be either an engineering or a commercial success, when it shall have become endowed with living activity. Nine and a-half miles between Listowel and Ballybunnion will not suffice to demonstrate that any railway scheme, however plausible on paper, will be found suitable for lightning express trunk railway service.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 500.)

"Sealing-in" the filament is the next process to be described. The precise details of the process depend upon the way the filament is mounted, whether the platinum wires are joined together by glass in any way, and whether the lamp is to be "capped" or is to have the platinum wires formed into loops at the bottom or sides of the neck of the bulb. First of all, the exhausting tube, if closed up, must be opened by cutting off the tip. This tube is now used for holding the bulb, and it makes a very convenient handle by which to rotate the bulb in the flame. The neck of the bulb is then heated by rotating it in the blow-pipe flame, so as to soften the glass at a short distance from the bulb. When soft the superfluous piece of neck is pulled away with the right hand, while the left still holds the bulb in the flame, so that the piece of neck is severed from the rest, leaving the bulb with the short remaining neck closed up. If too long a neck still remains, more may be removed by again heating and drawing it off by means of a small piece of glass rod or a bit of waste glass from a former operation. The end of the short neck has now to be opened for the reception of the filament. It is again held in the flame, and when soft the small tube is blown through somewhat violently, so that a hole is blown or a large and very thin bulb

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

Digitized by Google

is formed, which can easily be removed with the end of a file or other instrument, A, Fig. 29. The opening produced is probably too small to get the filament through, and it must therefore be enlarged. This is done by pressing out the sides when soft with the end of a file, as B. One of the glass blower's most useful tools is a small fine file, as with it he can scratch the glass in order to cut it at any point, while the end which is intended to go in a handle can be used for moulding the glass when soft. The filament already mounted on the platinum wires is next carefully inserted through the opening. It may be handled by the wires by means of a small pair of pliers. When far enough in the bulb the wires are held against the glass at the end of the opening and held in the flame. As soon as the glass at the point of contact is soft, the wires will adhere to it, and the pliers can be laid down. The next thing is to close up the opening. It will close up of itself if sufficiently heated, but it may be assisted by pinching with a pair of spring nippers made for the purpose. If this is done there will be rather large corners formed, as in C, which can be cut off while soft with a pair of cutting nippers. To make the seal good and neat it will require several times heating and blowing out by blowing through the small tube.

If the lamp is to be "capped," the end must be formed so that the plaster used in the cap will have a good hold on the lamp. It must be shaped so that it can neither be pulled out of the plaster nor twisted round in it. The simplest way of insuring this is to make a flat piece in the way just described with a thickened end, as in D, E. The flat end prevents the lamp from turning round, and the thickened part is surrounded by the plaster and cannot be pulled out. The

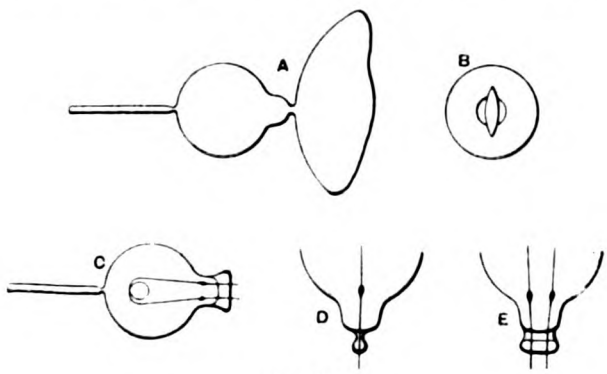

Fig. 29.

thickened end may be made by melting a piece of glass rod, and winding a string of the semi-fluid glass round the end of the flat piece. Or, if the glass in the neck of the bulb be thick enough, it may be simply squeezed upon the wires, but squeezed thinner close to the bulb than at the end where the wires come through.

Some glass-blowers adopt a somewhat different method of sealing in. The filament is inserted in the opening in the bulb, as before, but is allowed to slip inside, wires and all. The neck is then heated, and drawn down quite small, and sealed up. A small hole is then made in the end by blowing through as before. The bulb is tipped up so that the wires protrude by the required amount. The small opening is then easily closed up as before. This is rather a neater method than the other, but is more likely to injure the filament. If the wires are to be formed into loops, they may be bent into shape before the filament is put into the bulb, or the loops may be formed after the seal is made. The first method produces the most uniform loops. Care must be taken in forming the loops that they are of equal size, or there may be a difficulty in making contact with the holder to which the lamp will eventually be attached. If the wires are to be brought out at the sides of the neck, a similar method may be used, the filament being inserted as before, and the ends of the wires pushed back through small holes made in the neck. Another method is to cut the neck off at the place where the wires are required to come out, and then to put in the filament with the wires reaching over the sides, and melt the neck on again.

The filament having been sealed into the bulb, the next process is that of exhausting the air. This process is, perhaps, the most important of all, as upon the excellence of the vacuum produced depends, to a very great extent, the life of the filament. It is, moreover, the most costly per lamp of any of the processes.

It is necessary that the air be removed from the bulb, primarily, on account of the combustible nature of the filament. If a carbon filament is heated to incandescence in air, by a current of electricity, it rapidly burns away. Even if the air is removed as far as possible by exhausting with a good mechanical air-pump, there will be sufficient left behind in the bulb to burn the filament enough to speedily cause its breakage. It is necessary to produce a very much better vacuum than can be obtained by any ordinary mechanical vacuum pump. A very small quantity of air left behind in the bulb will be enough to burn the filament slightly, and thereby shorten its life.

It has, at various times, been proposed to fill the bulb with nitrogen gas, and then to only partially exhaust. In this way a residual atmosphere of nitrogen could be left behind,

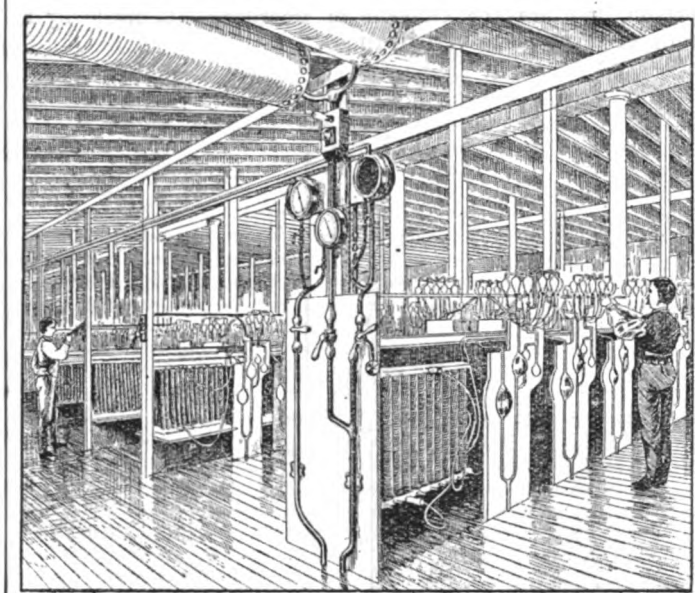

Fig. 30.—Sawyer-Mann Pump Room.

which would be incapable of burning the filament. Another advantage of the method would be that the exhaustion, not requiring to be carried to a very high state, could be done very quickly with a mechanical air-pump.

When the vacuum is not good, and there are consequently convection currents set up within the bulb, the law of $c \propto d^2$ does not appear to apply, or, at any rate, it becomes useless for the practical purpose of calculating the sizes of filaments. The actual amount of the effect of convection depends not only on the pressure of the gas but on the size of the bulb. If the bulb is small, the gas within it will get much hotter, and the filament will also be hotter than if the bulb is large, when there is a greater quantity of gas to be heated and a larger surface of glass for it to cool against. It therefore becomes necessary that the vacuum in a lamp shall be so far perfect that convection currents are absent altogether. In order to produce such a vacuum it is necessary to use what are known as mercurial air-pumps, mechanical air-pumps not being good enough for the purpose. Of course, it is impossible to obtain a theoretically perfect vacuum, but with the mercurial air-pump such a degree of exhaustion can be produced as to reduce the pressure of the gas to something unmeasureable, and to entirely remove all signs of convection.

The mercurial air-pump, although only within the last few years brought to a state of efficiency—it cannot yet be called perfection—is by no means a recent invention. It was used more than two hundred years ago. In the seventeenth century, Torricelli showed how a vacuum could be produced by filling a tube, something over 30in. long and closed at one

Digitized by Google

end, with mercury and then inverting it, while temporarily closing the open end, and placing that end under the surface of mercury contained in a cup. The mercury in the tube then descended until it stood at what is now called the "barometrical height" above the level of the mercury in the cup. The enclosed space within the tube above the top of the mercury contained, therefore, a vacuum, as in an ordinary barometer. A vacuum so produced is always now called a "Torricellian" vacuum.

Progress from that time was slow. It was not until 1865, when Sprengel brought out his well-known form of pump, that high vacua were easily obtained, although, ten years previously, Geissler had invented the pump which is called by his name, and which, in a modified and improved form, is now found to be equal, if not superior, to the Sprengel pump.

Anyone who wishes for full information on the development of the mercurial air-pump from the time of Torricelli, must study the lectures delivered in 1887, before the Society of Arts, by Prof. S. P. Thompson. A reprint of these lectures, from the *Journal* of that Society, is published by Spon. Anyone reading these lectures will understand that the modern forms of pumps are in no case the invention of any individual person, but are the outcome of improvements made by a number of people at various times.

FIG. 31.

The illustration (Fig. 30) gives a view of the pump-room of the Sawyer-Mann lamp factory in New York, reproduced from the New York *Electrical Review*.

For factory use, Mr. Swinburne used the arrangement shown in Fig. 31. The shaft B passes through a rubber cork L, into the bottle M, to within a very little of the bottom. A tube, N, also passes through the rubber cork. In starting the pump the cock O is turned, thereby connecting the pump with the mechanical vacuum pump. Air is therefore drawn out of the pump and the lamps, and mercury from the bottle M rises in the shaft B until it forms a column nearly 30in. high, reaching to a point a little below the junction of the tube G with the shaft B. Air under pressure is then admitted at N. The mercury is consequently forced from M up the shaft B, filling the bulbs A and F, until it reaches the valve chamber K, driving the air before it. At this point, the full air pressure being exerted, the mercury rises no higher. The air pressure required is not great, only about 6lb. or 7lb. to the square inch, representing a rise of the mercury column from G to K of 12in. or 14in. By an automatic arrangement, the pressure is then taken off, the tube N being connected with the outside air. The mercury consequently descends, the valve K closing and remaining sealed, with some mercury left behind in the valve chamber. The mercury drops to below G. The air left in the lamps therefore expands into A, and the operation is again repeated.

Fig. 32 gives a view of part of a pump-room, with this type of pump, erected by the author. The pumps are of a rather large size, containing nearly 30lb. of mercury each.

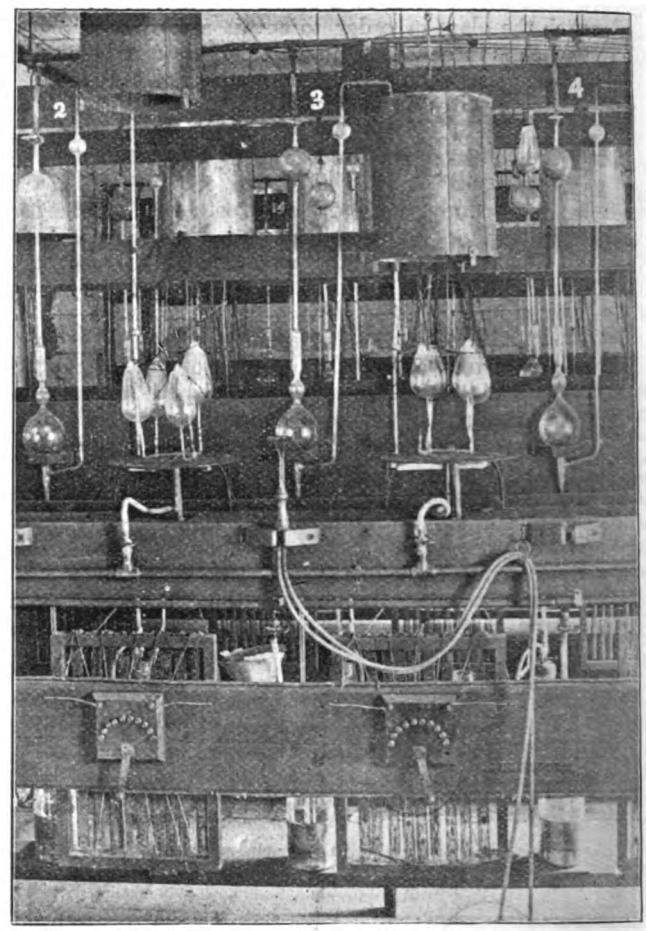

FIG. 32.

They differ from that shown in Fig. 31 in some of the details. For instance, instead of the rubber cork L in the reservoir M, the arrangement shown in Fig. 33 was adopted. A is a hard wood cap, fitting the top of the jar B, and having two metal tubes, C and D, passing through it. These tubes are

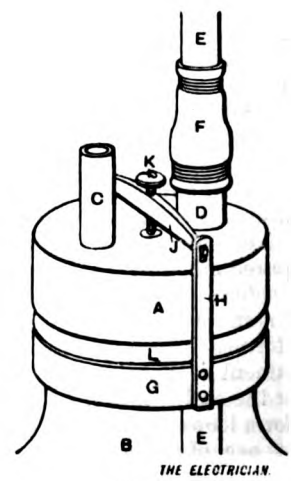

FIG. 33.

screwed in so as to be quite air-tight. E is the shaft of the pump, passing through D to the bottom of the jar B. F is a piece of rubber tube, bound tightly with wire round D and E, thereby making an air-tight joint. G is a metal collar round the neck of the jar, immediately under the rim L. H is an upright strip of metal fixed to G, there being another similar

Digitized by Google

one on the farther side. J is a metal cross-bar, extending at each end into slots in the uprights H. K is a screw passing through J. A rubber washer is placed between the cap A and the top of the jar. The screw K is tightened until the cap is pressed down, so that the joint is air-tight. The air pressure pipe is connected to C. This arrangement was found to be much more reliable than the simple rubber cork, owing to the latter not unfrequently working loose and allowing the air to escape.

(To be continued.)

THE ELECTRICAL RESISTANCE OF METALS AND ALLOYS AT TEMPERATURES APPROACHING THE ABSOLUTE ZERO.

BY PROFS. J. DEWAR AND J. A. FLEMING.*

In the autumn of last year we published a short account of experiments made by us during the previous summer on the electrical resistance of metals, non-metals, and alloys taken at the temperatures produced by the evaporation of liquid oxygen when boiling under normal or under reduced pressures. These experiments, which were merely preliminary, revealed, however, the nature of the difficulties to be overcome in repeating and following out this work. During the past year a much more extended series of investigations have been carried out by us on the same subject, but with more complete appliances for the production of the large quantities of the liquid gases necessary as refrigerating agents, and with greater care in the preparation of the metallic wires used in the physical measurements to be made. This inquiry is still far from complete; but the results are of considerable interest as far as they have gone, and we consider it may be desirable to place on record a portion of the conclusions at which we have arrived. The general object of this research may be stated to be the determination of the specific electrical resistance of metals and alloys between the limits of temperature of about 200°C. and the lowest obtainable temperatures approaching the absolute zero. We particularly desired to investigate the variation of resistance with temperature below −100°C, and to determine the form of the temperature-resistance curves as the temperature is lowered down to the lowest points obtainable by the evaporation of liquid oxygen boiling under reduced or normal pressure. The two variables with which we are concerned being, therefore, specific electrical resistance and temperature, we may point out in the first place how each of these has been defined and measured in tabulating the results.

There are, as is well known, two ways in which we may define specific electrical resistance. The first, called the volume-specific resistance, is defined as the resistance of one cubic unit of the material taken between opposed faces of the cube. In this method of defining it the specific electrical resistance is given as the resistance in ohms, or electromagnetic units of one cubic centimetre of the material between opposed faces. The second, called the mass-specific resistance, is the resistance of a wire of the material of a certain length and weight. In this second method of defining it, it is generally stated as the resistance in ohms of a wire of the material one metre in length and weighing one gramme. When it is desired to compare together, or state the specific resistance of materials in the form of wires, of which the diameter is not very different from one millimetre or larger, and length, say, of one metre or more, there is no doubt that the most convenient way of stating the results is by means of the mass-specific resistance; and since the mean specific gravity of wires of this size can always be determined with a very fair degree of accuracy, the volume-specific resistance can easily be deduced. If, however, as in the case of our own experiments, the conditions necessitate the employment of very fine wires of about 0·08mm. to 0·25mm. in not very great lengths, the probable errors on determining the weight per metre, and especially the specific gravity, are very considerable. We therefore preferred to face the difficulty of determining the mean diameter of the wires employed, and state our results in terms of the volume-specific resistance. One part of the work consisted, therefore, in the determination of the mean cross section of a series of very fine wires prepared from the metals and alloys under test, taken by means of an optical method, to be presently described. From this mean cross section and the length, we are able to state, when the resistance is known, the volume-specific resistance of the material. Since, however, the measurements of length and diameter were all taken at temperatures between about 15°C. and 20°C., it will only be possible to express the true volume-specific resistance at any assigned temperature when we know the changes in dimensions which the material undergoes when heated or cooled. The true volume-specific resistance of the material at any temperature is the resistance in electromagnetic measure between opposed faces of one cubic centimetre of the material taken at that temperature. Pending, however, the determinations of the temperature-change in dimensions of the metals and alloys employed, we omit the correction (no doubt small) due to the change of dimensions, and state our results in terms of the electrical resistance in electromagnetic measure of one cubic centimetre of the material measured at 15°C., the said electrical resistance being determined at the various temperatures to which the material is raised or lowered. In the next place we have to consider the question of temperature-measurement. As the lowest temperatures reached by us in these experiments were temperatures at which air liquefies under ordinary pressures, the practical employment of the air-thermometer was surrounded with many difficulties. Ultimately it may be necessary to define the temperatures attained in terms of the absolute thermodynamic scale. But even the employment of the constant reduced-pressure hydrogen thermometer-scale, which may be taken as giving us the nearest practicable approximation to the true thermodynamic scale, is a matter in which extreme care will have to be employed in obtaining and interpreting results. We have been led, however, by one part of our results to see that, for our purpose here, by far the most practical method of defining the temperatures employed is to state them in terms of the variation of the specific resistance of one standard metal.

In the practical determination of temperature we select a thermometric substance, it may be air, hydrogen, mercury-in-glass, or some other material, such as a double metallic junction of thermoelectric materials, and we select also a thermometric quality, such as the change in pressure, change in apparent volume, or thermoelectric difference, and define our temperature by the temperature-change of the thermometric quality of this thermometric material. There is, therefore, nothing to prevent us from selecting as a measure of temperature the change in electrical resistance of a wire of a standard material and defining temperature in terms of the change. It will afterwards be possible to translate the temperatures so measured into their equivalents on the absolute thermodynamic or air-thermometer scales. Our experiments at low temperatures have confirmed us in the view that the most convenient method of determining and stating such temperatures is in terms of the change of specific resistance of pure platinum. H. L. Callendar and Callendar and Griffiths have carefully examined this matter for temperatures from about zero Centigrade upwards to about 1,000°C. Callendar has indicated the possible causes of the discrepancies in the results obtained by previous observers in the use of the platinum resistance-thermometer, as originally suggested by Siemens; and he has shown that a properly arranged pure platinum wire may be employed to measure temperatures, and may have its fixed points determined. We have in like manner found that a wire of pure soft annealed platinum may be cooled again and again to the lowest attainable temperatures, and heated up to high temperatures, without suffering any permanent change in its specific resistance after the first careful annealing has been made. This property is not, however, confined to pure platinum, but is equally possessed by other properly annealed metals. There are, of course, good reasons for giving preference to platinum in the construction of resistance-thermometers; but, on the other hand, it is possible that for low temperatures chemically pure nickel, prepared by the process discovered by Mr. Ludwig Mond from nickel carbonyl, will prove to be of great utility on account of its very large mean coefficient of variation of resistance with temperature. It is, however, clear that a wire of pure platinum which has been carefully annealed possesses a definite electrical resistance at each temperature to which it is exposed, and may be made use of as a thermometric body with great convenience. Callendar has introduced the useful term *platinum temperature* to denote temperatures measured with the platinum resistance-thermometer. On this scale the temperature is defined as follows:—Let R_0 be the electrical resistance of a given wire of pure platinum at zero Centigrade, that is when immersed in melting ice, and let R_{100} be the resistance of the same wire at 100°C. Then an increment of temperature, which causes a change in the resistance of the platinum equal to $\frac{R_1 - R_0}{100}$, is called one degree of platinum-temperature. If pt denote any temperature measured on this platinum-scale, and R be the resistance of the wire at that temperature, then

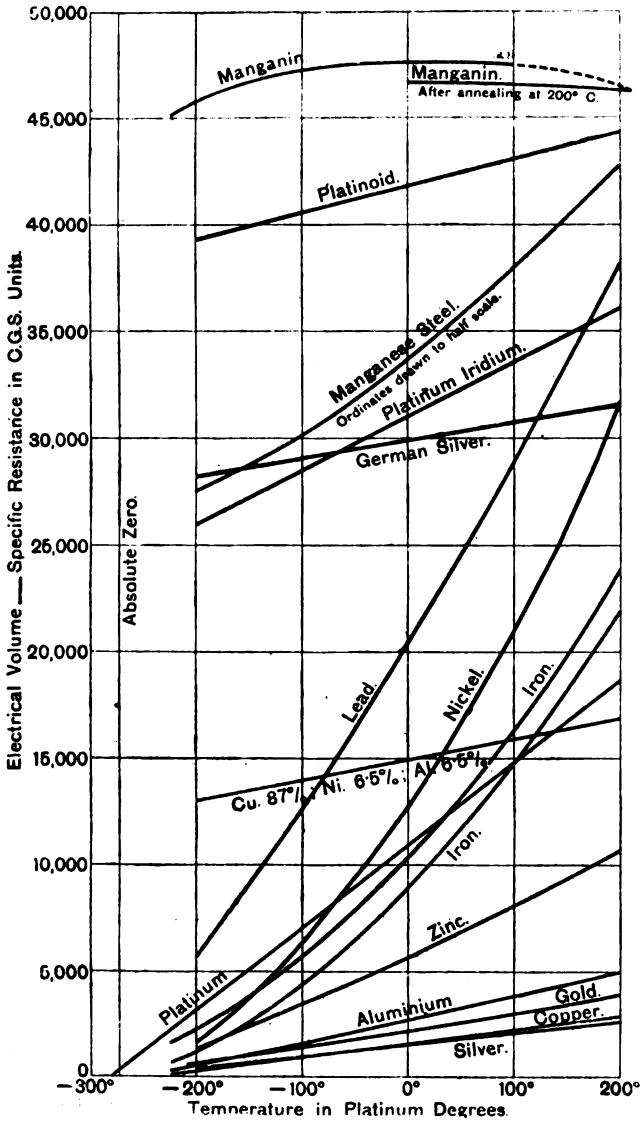
$$pt = \frac{R - R_0}{R_1 - R_0}\ 100.$$

Hence, if we take any straight line as a temperature-axis, and at any two points erect perpendiculars to it, which are proportional to the resistance of the platinum wire at 0°C. and 100°C., and draw through the summits of these ordinates a straight line cutting the axis of temperature, we may define temperature as follows:—Divide the horizontal interval between the ordinates into one

* Abstract from *Phil. Mag.*, September, 1893.

Digitized by Google

hundred equal parts, and continue the division on the scale backwards to the point at which the inclined line cuts the temperature-axis. Measure the resistance of the platinum at any temperature, and find the ordinate representing this resistance : the foot of this ordinate marks the temperature on the platinum-scale. Callendar has shown that the difference between temperatures measured on this platinum-scale and the corresponding air-thermometer temperature is very nearly represented by a parabolic function of the air-thermometer temperature. It remains to be seen if all pure platinum wires give the same platinum temperature. We have found slight differences between the specific resistance and temperature-coefficients of platinum wires of different diameters, prepared with the greatest care, and supposed to be equally pure, but which differences do, no doubt, depend upon slightly different degrees of hardness or purity. These differences are sufficient to make small but quite evident differences between the platinum



Variation of Electrical Resistance of Pure Metals and Alloys with Temperature.

temperatures as determined by these different platinum wires. These differences, however, are not more marked than would be the case with temperatures measured by different mercury-in-glass thermometers. We have accordingly selected one of our platinum wires as a standard thermometer, and have referred all our measurements of temperature to it, and subsequently we may determine the equivalent temperatures on the air-thermometer scale. This platinum wire we refer to subsequently as the "thick platinum" wire. In the chart appended to this Paper, the abscissæ of temperature are, therefore, platinum-temperatures as measured by our standard platinum wire. The general nature of the measurements made consisted, therefore, first, in the measurement of the length and mean diameter of a fine wire of a metal or alloy of carefully-prepared quality ; secondly, in the measurement of the resistance of this wire when immersed in a bath, giving it the necessary temperature ; and thirdly, the determination of this temperature of the bath by the measurement of the resistance of the standard platinum wire before and after the measurement of the given wire. From the results of these observations we could deduce the volume-specific resistance of the material at certain platinum temperatures, and plot a series of curves to represent the variation of this resistance with temperature.

Passing on to further details, we proceed to describe briefly the preparation of the metals and alloys in the required state of purity, and the construction of the resistance-coils suitable for the purpose of these experiments and the mode of making the required measurements. Our previous experiments had shown the necessity for the greatest care in the preparation of the metals. The term *pure* is, of course, a relative term, and absolute purity in a chemical sense is, of course, a most difficult matter to secure ; but every care has been taken to arrive at the greatest possible purity in the majority of the metals employed. In this part of the work we have been greatly aided by several friends. Foremost amongst these, we are especially indebted to Mr. George Matthey, who has given us invaluable aid in the preparation of a large series of metals in a state of great purity. Mr. J. W. Swan has furnished us with many samples of electrolytic copper and silver prepared by himself by his own special processes. From Mr. G. Addenbrooke we received samples of aluminium and aluminium alloys, which have been of use to us ; and Col. Dyer, of the Elswick Ordnance (Armstrong's) Works, has kindly sent us samples of iron prepared with very great care. Having these materials in our possession, they were in most cases drawn into wire for us by Messrs Johnson and Matthey, and in some cases, such as those of lead, tin, thallium, and some others, the metals were pressed into wire in a steel press by the hydraulic 50-ton testing-machine in the Mechanical Laboratory of University College, London. These different wires had a diameter varying from 0·08mm. (3 mils) up to about 0·25mm. (10 mils), and lengths of from 1 to 3 metres.

The next step consisted in measuring the mean diameters. For such fine wires no ordinary process of callipering was sufficiently accurate. After many experiments, the following method of obtaining rapidly the mean diameter was perfected :—A compound microscope had the eye-piece removed, and the substage under the object-glass fitted with a large cork, bored out in the centre with a hole, and having two small glass tubes inserted in the sides. This cork was so fixed to the stage that when a wire was drawn through the small tubes, it passed across the field of the objective. The stage had a rack-work motion, which enabled it to be moved to or from the objective ; but this last remained fixed relatively to the stand of the microscope. The microscope being placed horizontally, an incandescent lamp was placed behind a condenser lens at the back of the substage, and an image of the wire projected by the objective on to a sheet of fine hot-pressed drawing paper placed a yard away from the lens. The objective which formed this image always remained fixed relatively to the screen, and the image was focussed by moving the substage which carried the wire. The magnification of the image was about 300 times linear, so that the image of a wire about 0·003in. in diameter could be made to appear 1in. in diameter. A 2in., 1in., or ½in. objective could be used as desired. This optical image or shadow could be made exceedingly sharp and well defined, and could be measured with a pair of dividers to much less than 1 per cent. In order to infer the real diameter of the wire from the diameter of the image the following method was employed :—A series of five steel-wire gauges was made formed of round parallel steel wire about 10 centimetres in length, rammed into wooden handles. These handles were planed off on one side flat. These gauges varied in diameter from about 3mm. to 0·04mm. The gauges were sent to the Board of Trade Standardised Laboratory, and the diameters of the steel wires officially measured with their Standard instruments along axes parallel to the flat side of the handle, and taken at the centre of the wire. This being done, we had a series of standard gauges whose diameter in one definite position was known to the $\frac{1}{10000}$th of an inch. These gauges were marked A, B, C, D, E. Two more similar gauges were prepared, called F and G, of smaller steel wire, and a number of observations of the diameters of F and G relatively to E were made by means of a micrometer-microscope belonging to the Physical Laboratory of University College. Many observations were also made of the relative diameters of the images of gauges E, F, and G when projected by the projection microscope, the gauges being in the same focal position relatively to the objective and screen. These experiments, which were most carefully made, sufficed to establish the diameters of the steel gauges F and G in the centre and parallel to the flat side of their handles, in terms of the Board of Trade measuring instrument, and the final mean result expressed in centimetres, is that the central diameters of gauges F and G, parallel to the flat side of the handle, are as follows :—

Central diameter of gauge F = 0·03966 of a centimetre,
Central diameter of gauge G = 0·03959 of a centimetre,

taken at about the normal temperature 15°C. The process of measuring the mean diameter of any wire was then as follows :—The

appropriate length of the wire being cut off and measured against a standard-metre scale, it was drawn through the field of the microscope, the smallest gauge, F or G, being placed in the same focal plane and parallel with the wire. The gauge was placed with the flat side of the handle parallel with the screen and the centre of the steel gauge in the centre of the objective field. We had then on the screen the images or shadows of two objects, one a wire of steel of known diameter, and the other a wire of unknown diameter; the diametral planes of each wire being in the same focal plane of the lens. The diameters of the images of the steel gauge and the wire were then carefully measured with dividers and expressed in terms of some arbitrary unit. The ratio of these apparent image-diameters was taken as the ratio of the real diameters of the wire and the gauge. The measurement of the diameter of the wire was taken about every five centimetres in the case of very uniformly drawn wires, and more frequently in other cases. Generally about 20, and sometimes 60 diametral measurements were taken in the metre length of the wire to be measured, and as the wire was turned round its long axis in passing through the field of the microscope the diametral measurements were taken in numerous directions. The mean of all these measurements gave a close approximation to the mean diameter of the wire. As an instance of the close agreement of the results by this method, and those obtained by the density method, we may give the following comparison of the determination made of the mean diameter of a certain high conductivity copper wire about 0·01in. in diameter. Mr. J. W. Swan sent us this wire, and determined its mean diameter by a very careful measurement of its length and mean density. Our measurement of the mean diameter of this wire was 0·02609cm., and his was 0·02608cm., agreeing thus within 1 part in 2,600. By the use of a suitable objective this method was applicable to the smallest wires used as well as to the largest. Each wire having had its mean diameter and length thus ascertained, the mean cross-sectional area was calculated, and a reduction-factor obtained by which the reduced true resistance of the wire in ohms was multiplied to deduce therefrom the volume-specific resistance as above defined.

Furnished with these wires, the next step was to prepare suitable resistance coils, by which the resistance of the wires could be taken in a bath of liquid gas. In our former experiments, the wires of which the resistance was to be determined were wound on a rectangle of mica, having serrations or teeth cut upon the edge, and the ends of the wire were then soldered to stout copper connections. For many reasons this proved to be an undesirable method. Many wires, such as aluminium, were easily broken by the sharp bend in the wire, and other soft wires, such as lead, were deformed at the same point of bending. In preparing coils for the purpose we had in view it was necessary to keep them small, so that they might be easily contained in a moderate-sized vacuum-jacketted test tube in which the liquid was held. For obvious reasons also, any large amount of non-conducting material round the wire was objectionable. After some trials the following method of constructing the resistance coils to be used was adopted, and answered very well. Stout high-conductivity copper wire of 4mm. diameter was cut into lengths, and pairs of these wires bent up and bound together at the middle, but insulated from each other with india-rubber tape. The ends of the wires were well tinned, and the bottom ends nicked. A very thin sheet of vulcanised fibre was then bound round the bottom part of the copper rods, and sewn to them by silk thread. This formed a thin cylinder on which the wire to be tested was carried. A stout silk thread was then wound, spiral fashion, round the cylinder. The wire to be tested, generally one, two, or three metres in length, was then carefully wound on the fibre cylinder, in between the silk thread, the several turns of which kept the turns of wire from becoming short-circuited. The dimensions of the cylinder of vulcanised fibre varied according to the length of wire used, but was from two to three centimetres in diameter and four to five centimetres in length. A large number of such bobbins having been prepared, the next step was to anneal the wires on these coils. The so prepared resistance coils were immersed in melted paraffin wax, and kept at a temperature of 200°C. for some time. These being slowly cooled, they were annealed, and at the same time the insulating portions of the coils well saturated with paraffin.

The resistance measurements were carried out by means of a Wheatstone bridge by Messrs. Elliott Bros. The coils of this bridge were of platinum-silver, and adjusted to read in standard ohms. The coefficient of variation of resistance of the coils of the bridge with temperature was determined, and found

Digitized by Google

to be 0·031 per cent. per degree Centigrade. The temperature of the bridge-coil box was always taken at the time of making each set of measurements, and the proper correction applied. Another correction of importance was that for resistance of the connecting leads and the copper terminals of each coil. A loop of copper wire was prepared of the same metal, and of the same total length, as the standard size employed as terminals of each resistance coil. This blank was always measured before and after each set of experiments on the coils, and so arranged that it was under the same temperature conditions as the terminals of the coils. This, together with the resistance of the short thick bridge leads, is always called "resistance of connections" in the Tables, and is a correction invariably applied in each case. The galvanometer employed with the bridge was a Pitkin-Holden galvanometer of the suspended coil type, having a resistance of about 10 ohms, and nearly perfectly dead-beat. One cell of a Helsen dry battery was used, and the usual battery and galvanometer keys inserted in their respective circuits. The temperatures above zero Centigrade were obtained by immersing the coils in a beaker of melted paraffin oil standing in a large zinc bath full of water. This water was heated to varying temperatures up to about 98° C. The paraffin was kept well stirred, either by a mechanical stirrer, or, better, by passing slowly bubbles of air through it from an elastic bag full of air. The temperature of the paraffin oil was taken by a mercury-in-glass thermometer, the scale readings of which were corrected for us by Mr. Casella by comparison with those of a standard mercury thermometer which had been checked at Kew. Temperatures close to zero Centigrade were chiefly obtained during the long frost in January, 1893, by placing the coils in paraffin oil in beakers which were placed in the zinc bath filled with broken ice. Coils waiting to take their turn to be measured were kept standing in other beakers of paraffin oil also placed in the same large zinc bath. Those who have conducted similar experiments know well that the great difficulty in such resistance measurements is to make sure that the coils have reached the temperature of the surrounding fluid, and to avoid changing their temperature by the current employed to measure them. For this reason very weak currents have to be used with the bridge. The temperatures below zero Centigrade were obtained by the use of a bath of carbonic acid snow, and ether, or paraffin oil, which gave temperatures according to desire from 0° C. down to about −78°C., and a series of measurements was thus made at about −40° and 78°. By the employment of liquid ethylene a temperature of −100°C. could be reached. Liquid oxygen was then employed as a refrigerating agent to lower the temperature of the resistance-coils to about −182°C. The liquid gas was contained in vacuum-jacketed flasks or test-tubes in which the resistance-coil was placed. Temperatures lower than the above limits were obtained by closing the mouth of the vacuum-jacketed test-tube with a tightly fitting india-rubber cork and producing a partial vacuum above the liquid oxygen. In these experiments the resistance coils were therefore immersed in liquid ozygen boiling under a very reduced pressure, as low as 14mm. of mercury. At all times great care is necessary to preserve the coil entirely immersed in the liquid gas. If the coil is only partially immersed thermoelectric effects are set up, in some cases of such a magnitude as to entirely vitiate the measurements of resistance. Hence the necessity for an abundant supply of the liquid gas. In some of the sets of experiments several litres of liquid oxygen were used up. In the above set of measurements about fifty coils in all were wound, and the measurements of each coil often taken several times at the same temperature. In those instances in which the temperature of the bath was below zero Centigrade the resistance of one of the standard platinum wires was measured in the same bath before and after each measurement of the resistance of the wire. The platinum-thermometer wire was thus placed under identical conditions with the wire under examination. In all the following Tables the temperatures in the columns headed pt are platinum temperatures taken with the standard platinum wire.

At this stage the authors give detailed accounts of their tests of samples of platinum, gold, palladium, silver, copper, aluminum, iron, nickel, tin, magnesium, zinc, cadmium, lead, and thallium.

The resistance curves of some of the above metals are delineated on the accompanying chart to a suitable scale. An examination of these lines will show that some of them are concave upwards and some concave downwards; those with the most marked curvature being the magnetic metals nickel and iron. The lines cross one another at low temperatures, and hence the order of conductivity of the metals at very low temperatures is different to their order at ordinary temperatures. At the lowest temperature reached the best metallic conductor is pure copper. It may be remarked that generally the best conductors amongst the pure metals are those that are most sonorous: silver, aluminium, gold, and copper would make good bells, whilst lead, thallium, tin, and palladium, which are the worst conductors, would be unsuitable for this purpose. The metals platinum, palladium, have resistance curves which have a marked concavity downwards when plotted in terms of Centigrade temperatures; whilst nickel and iron have a considerable curvature in the opposite direction. An examination of this chart will show that the conclusion reached in our former Paper is confirmed by these more careful experiments, viz., that the electrical specific resistance of all *pure* metals will probably vanish at the absolute zero of temperature.

An examination has also been made of a large number of alloys of known composition, and as the details are too numerous to tabulate in full, we append two Tables (I. and II.) which will show the volume-specific resistance in C.G.S. units of these various alloys at different temperatures stated in terms of platinum temperatures. At the same time the composition of the alloy is given. Also we add a Table III., in which the volume-specific resistance of each alloy is given at 0° C., and the temperature-coefficient at 15° C. The resistance-curves of these alloys are shown in the chart. Concerning these curves we may draw attention to the fact that the curve of Hadfield's manganese steel has a remarkably sudden change of curvature at about −40° C. It will be important to investigate the magnetic qualities of manganese steel at a temperature of from −30° C. to −80°, and see, if possible, what other physical changes take place at the time when the temperature-coefficient undergoes a rapid change. It will also be seen that the alloy manganin has a curve which has a maximum at 16° C. Hence manganin has a zero temperature-coefficient at 16° C., but a positive coefficient below that temperature, and a negative one above. It is very interesting to note the effects of the various constituent elements in the alloys. An admixture of 6 per cent. of silver with aluminium has a much greater effect in changing the specific resistance than 6 per cent. of copper, whilst 3 per cent. of aluminium has a greater effect still in changing the character of copper. We have collected together into Table IV. the volume-specific resistances of the pure metals, and also their mean temperature coefficients between 0°C. and 100°C.

In conclusion we desire to express our indebtedness to Messrs. J. and D. Morris for the valuable assistance they have given us in the conduct of this research, and in the reduction and graphic description of the numerous observations. We hope, in a future communication, to be able to state the results of similar observations at still lower temperatures.

THE PRACTICAL MEASUREMENT OF ALTERNATING ELECTRIC CURRENTS.

BY PROF. J. A. FLEMING, F.R.S.*

(Concluded from page 507.)

IV.—*Measurement of Alternating Current Energy.*

In this fourth and last lecture I propose to discuss the practical measurement of alternating current energy and alternating current quantity. In so doing, we shall begin by dealing with the easier problem in the measurement of such quantities, viz., when the circuits to which the power or current is being supplied are non-inductive, and then proceed to consider the more difficult case, in which the circuits are inductive circuits, such as the primary circuits proceeding out from alternating current stations.

Instruments for the measurement of alternating-current energy or quantity are called simply meters, and they are classified into ampere-hour meters and watt-hour meters. A complete classification of all the different forms of meter already invented would be a rather difficult thing to make on a perfectly correct basis. I shall give you presently an approximate classification. In the first case, we will consider the simplest forms of meter, which may be called graphic ammetersand wattmeters. Of these two, the Holden ammeter and Mengarini wattmeter are good examples In these instruments an arm carrying a pen is displaced over a paper-covered drum, which is revolved uniformly in 24 hours by a clock. The motion by which the pen is displaced is regulated by a part of the instrument which is simply an ammeter or a wattmeter, and the displacement of the pen is proportional to the current or the power passing through this measuring part. When, therefore, the diagram is cut off and unrolled, we find on the paper a curve which represents, by its ordinates, either the power or the current at any instant; and, if the whole area of the curve is integrated, then such area represents the whole energy or quantity which has passed through the meter in 24 hours. These instruments have the advantage, therefore, that we practically record two quantities at once; and they serve two purposes, of indicating the instantaneous current or power, and the total current quantity or energy; but they have the disadvantage that they are not self-integrating.

Next in order of simplicity are the self-integrating ammeter and self-integrating wattmeter. One of the simplest of these self-integrating ammeters, but which is, however, available only for the measurement of alternating current quantity, is the well-known Shallenberger meter. The principle of the Shallenberger meter is not a difficult one to understand. It consists of a small transformer, one coil of which we may call the primary, and which is in series with the circuit in which the current to be measured is flowing. The core of this transformer consists of a little soft iron disc, which is capable of revolving on an axis. This axis is geared at the top with a counting mechanism, which records the number of revolutions of the disc, and at the bottom there is a vane or fan of thin aluminium, which serves to retard the rotation of the disc. The secondary circuit of this transformer consists of a small coil of copper, which is closed upon itself, and which is placed with its axis inclined at 45deg. to the axis of the primary coil. When the primary current flows through the primary coil it does two things—it magnetises the core, and it induces a secondary current in the closed secondary circuit. It is not difficult to show that the phase of this secondary current must be about 90deg. behind the phase of the primary current, and also that the magnetism of the iron core, which is in a direction at right angles of the plane of the primary coils, also lags in phase behind the primary current by about 90deg. The magnetism of the core and the induced secondary current are, therefore, in step, and are in such directions that the axis of the disc is always being pulled round by the induced field of the secondary coil. If, then, there were no friction of any kind, the iron disc would be continually accelerated in speed, but since the air friction varies approximately as the square of the velocity, and since the mean driving force is proportional to the mean square of the current strength, it follows that the total number of revolutions which the disc makes in any given time is proportional to the total mean quantity or ampere hours which have passed the primary circuit. The meters can, therefore, be calibrated by a constant in such a way that they read directly ampere hours, and if the pressure between the mains is kept constant, they may be graduated to read in Board of Trade units.

These meters are very simple to construct and very fairly accurate in performance, and they have, therefore, come into extensive use. The velocity of the disc being at any time proportional to the mean current passing through the meter, we can, if the current is kept tolerably constant, employ the instrument as an ammeter. By moving the position of the secondary coil a little adjustment can be made in the meter for change of frequency, and the meter can be calibrated for the particular frequency for which it is intended to be used. The next meter in order of simplicity, and very similar in principle to the Shallenberger, is the Wright-Ferranti meter. It is also a self-integrating ammeter; it measures at any instant the mean square current, and gives us the mean quantity which is passed through the meter. The indicating part of the meter consists of a wheel with a light iron rim. This wheel is nearly embraced by two curved horns of laminated iron. These horns spring from the corners of a rectangle of laminated iron. This laminated iron rectangle is wound over on all four sides with two coils of wire. Through one of these coils the current to be measured passes, and the other coil is a shunt coil, the function of which I shall describe presently. The arrangements of the coil are such that any moment the ends of the curved horns are opposite magnetic poles. On these curved horns are placed copper rings. When the alternating current passes through the series coil it creates alternating magnetism in these curved horns, but owing to the eddy currents of the set up in these embracing rings, the magnetic lines of force are thrust outwards, making a lateral leakage field, which travels up the horn. This leakage field induces eddy currents in the iron disc, and the disc is thereby repelled in virtue of the electromagnetic repulsion set up between the horn and the wheel. When an alternating current is passed through the meter it tends to drive the wheel round with a speed which is proportional to the mean-square strength of the current, and, therefore, it follows that the number of revolutions made by the wheel at a given time is proportional to the mean quantity in ammeter hours which has passed through the meter at that time. Both the Shallenberger meter and the Wright-Ferranti meter require to be calibrated for the particular frequency for which they are to be used, and they only give Board of Trade units provided that the pressure is kept constant between the supply mains. The meter really reads quantity directly, and power only on the assumption of the constancy of pressure. I mentioned that there were two circuits on the electromagnet, and that one of these was the shunt circuit. The function of this shunt circuit is to supply the driving force which overcomes the friction of the counting train. If this shunt circuit were not present, there would be a frictional resistance to be overcome before the meter would start at all.

Another meter, of a tolerably simple character, also intended for measuring ampere hours, is the windmill meter, invented by Prof. Forbes some years ago. In that meter there is a coil of wire, which was heated by the current passing through it. This heated coil generates an upward current of air, and this upward current of air is made to turn round a very delicately constructed windmill with mica vanes. The counting train attached to the windmill records the number of turns in a given time. Although this may seem to have been a somewhat unpromising principle to apply, yet the meter in itself gave excellent results.

We turn next to the consideration of the second great class of meters, namely, the watt-hour meters, which are self-integrating. These self-integrating watt-hour meters may also be divided into two classes, continuously and intermittently integrating. Taking the last class first, this is well represented by the Frager meter. In this meter there are two distinct parts; first, the wattmeter part, which measures at any instant the power, and the integrating part, which integrates at intervals the power and the time. The wattmeter part consists of a wattmeter having a thick coil, which is a series coil, and a movable coil, which is suspended by a steel wire which is shunted across the circuit. The terminals of the shunt coil are connected to the two sides of the mains, and the current to be measured is passed through the series coil. Attached to the movable shunt coil is a long arm, and the displacement of this arm varies with the power passing through the instrument. Adjacent to the wattmeter and fixed on the same base is an electrical clock, which drives round a curved plate of metal, which is technically termed "the snail." On the end of the long projecting arm attached to the wattmeter is a small steel point. As the snail is turned round it passes underneath this arm, and if this arm is displaced, the length of the path of the pointer, when travelling over the snail, is proportional to the power passing through the wattmeter. The snail plate is so suspended that when the pointer passes over it it presses it down, and makes an engagement between the snail and the counting mechanism. At each revolution of the snail the counting mechanism is turned round by a number of revolutions which are proportional to the mean power or watts passing, and hence the total number of revolutions in any given time is proportional to the watt-hours which have passed through the meter. The snail revolves round in a period which is about three minutes, and hence the record is, as it were, made of the power passing through the wattmeter only at intervals of three minutes. If the current which is to be measured does not vary very rapidly, such an intermittent recording meter may be made to give very accurate results, but there are many cases, such as in theatres, where the amount of current passing through the meter is very irregular and

* Abstract of Cantor Lecture delivered before the Society of Arts, February, 1893.

Digitized by Google

rapidly varied. Under these conditions the wattmeter needle is thrown about in such a manner that the actual power recorded on the dials at every revolution is not always the true mean power passing in the interval between two revolutions, and the readings of the meter may, therefore, become very erroneous. Practice has confirmed these inferences, and although the Frager meter is under some conditions of use a very accurate meter, there are other conditions under which its readings are not to be depended on.

Coming next to the continuously recording watt-hour meters, we reach that class of meter which may be said to be the best adapted for general wants, and one of the most efficient of these continuously recording watt-hour meters is the one invented by Prof. Elihu Thomson. The Thomson recording wattmeter is a wattmeter in which one coil, called a series coil, carries the current to be measured. This series coil really forms the field-magnet of a very small electromotor. The armature of this motor is a beautiful one, having a small commutator and brushes of the usual kind, and this armature circuit, together with the external added resistance, constitutes the shunt circuit of the wattmeter. When the meter is attached to a circuit, the main current of which passes through the series coils, and the shunt coil being attached to the two mains, the armature begins to revolve. The shaft which carries the armature carries also a copper disc, which is embraced by three horse-shoe magnets. When the disc revolves, eddy currents are set up in the disc which retard its motion. The number of revolutions of the disc in a given time is recorded by the counting mechanism attached to the shaft. Then since the force driving the armature round is at any instant proportional to the power passing through the instrument, and since the retarding force is proportional to the velocity, it follows that the number of revolutions in a given time represents the watt hours that have passed through the meter. In order to overcome the constant friction of the train, there is a compound winding on the field-magnet, consisting of a few turns of the shunt coil, which is arranged in such a direction that the driving force due to the fixed and movable shunt-winding, tends to overcome the permanent friction of the armature shaft. By properly treating the permanent magnets it is found that they retain a constant magnetism for long periods of time. The meter is so arranged that when working on a 100-volt circuit the shunt coil has a resistance of 1,000 ohms altogether, and takes, therefore, 0·1 of an ampere. The loss in the meter, therefore, is only 10 watts, which is the power taken up in driving the meter. By properly arranging the shunt coil it is possible to make the constant of this meter perfectly constant for a very large range of its action, and one great advantage which this meter has is that it can be employed with both alternating and continuous currents. When properly adjusted this watt-hour meter is capable of very great accuracy in the measurement of alternating-current energy.

Reviewing, then, the whole of these meters, we may say that a rough classification of meters for the measurement of alternating currents may be made as follows :—

1. Graphic recording ammeters.
2. Graphic recording wattmeters.
3. Continuously recording ampere-hour meters.
4. Intermittent recording wattmeters.
5. Continuously recording wattmeters.

We may ask ouselves at this stage what ought to be the characteristics and requirements in a good commercial meter for the measurement of electric energy supply to houses for lighting and other purposes. Most persons without experience would probably say that the first requirement in a meter is accuracy ; but as a practical matter accuracy is not of so much importance as that the meter should never go far wrong. A type of meter which is capable of measuring, under some conditions, to 0·1 of accuracy, and at other times is liable to make errors of 150 per cent. in actual practice, is not nearly so useful as a meter which will not read closer than 1 per cent., and yet which, in actual practice, never proves to go more than 3 per cent. wrong. The next condition which a meter must comply with is that of the consumption of small power. Since the meter is connected to the circuit continually, if it absorbs power, the sum total of all these consumptions may amount to a serious item. We have pointed out, in speaking of voltmeters, that a continuous power absorption, say, of 20 watts, during the whole year amounts to a yearly consumption of 160 units of electric energy, and that, therefore, small power consumption is certainly an important item in appraising a meter. The third great requisite is that the meter ought not to require elaborate care and delicacy in fixing, and that it ought to be hardy enough to be easy of carriage. House meters have to be fixed in places which are sometimes subject to vibration and dampness, &c., and a meter for house purposes ought, therefore, to be hardy enough to stand these conditions. The fourth condition is that the meter must be so constructed in principle as not to be capable of being easily tampered with, or its indications made to vary, even when enclosed in a lock-up case. To the above requirements ought, of course, to be added the broad and general conditions of simplicity of structure and cheapness in price, as far as consistent with good workmanship.

I now turn to the important subject of the measurement of alternating current power when supplied to inductive circuits ; in other words, we have to study alternating current primary meters. In the distribution of alternating currents for commercial purposes, not only is it necessary to be able to measure the power or energy supplied to the consumer on the lamp circuits, but it is also necessary to be able to measure the power and energy sent out from the alternating-current station which is supplying, generally, transformer circuits. Hence, we have to consider the special difficulties of making such measurements on circuits which have a considerable self-induction, or in which the power-factor of the circuits is below unity. During the past year or two I have paid particular attention to this subject, in a long series of researches on the efficiency of transformers, and have thereby been led to study most of the various methods which have, from time to time, been proposed for measuring alternating-current energy. I do not propose to occupy the time in discussing any of the methods which, however well they look on paper, are yet, for some reason or other, inapplicable in practice, but to describe the methods which have proved themselves, in my experience, satisfactory and practicable in making these measurements. I have found that the two instruments for this purpose which are capable of being employed with very satisfactory rssults for the measurement of alternating-current energy on inductive circuits are the Thomson recording wattmeter and the Mengarini wattmeter already described.

Generally speaking, these measurements have to be made on high-tension circuits. Take, for instance, the very common case of an alternating-current station, supplying alternating current at a pressure of 2,000 volts on transformer circuits. One method of employing either of the above wattmeters as energy meters would be to place a non-inductive resistance of sufficient magnitude in series with a shunt coil, and to put the series coil in the series with one of the primary mains. In such an arrangement there would be certain disadvantages. In the first place, the Thomson recording wattmeter takes a current of about one-tenth of an ampere through the shunt, and hence we should have to add to the shunt coil, the resistance of which is about 1,000 ohms, another 19,000 ohms of non-inductive resistance, and then, when this was done, the power wasted in the whole of these shunt circuits would be 200 watts. If these shunt circuits were kept connected to the mains throughout the whole year, the waste of energy in these shunt circuits would be something like 1,600 Board of Trade units, and if we reckon the manufacturing cost of these at only 2d. a unit, it would cost something like £12 per annum merely to supply the shunt circuit with current. But this difficulty can be got over, and also the difficulty of constructing a large non-inductive resistance of 20,000 ohms, sufficiently well divided up not to be in any danger of breaking down with 2,000 volts pressure, by the adoption of a transformer to excite the shunt circuits in the way described in my last lecture. A small transformer is employed, transforming down from 2,000 volts to 100 volts, and as this transformer is only to supply one-tenth of an ampere on its secondary circuit, it can be made very small, not more than, say, a tenth of horse-power in capacity. It can, therefore, be made to waste not more than about 10 to 20 watts in itself. This transformer has its primary circuits connected across the primary mains, and its secondary circuit is connected across the terminals of the shunt circuit of the Thomson wattmeter, and so joined up that the current in the shunt circuit of the wattmeter is in the same direction and has the same magnitude as if the wattmeter were joined up simply on a 100-volt circuit in the ordinary way. The wattmeter in itself only wastes about 10 watts in its shunt circuit, and, therefore, the whole arrangement of the transformer and wattmeter can be made to waste not more than, say, 25 to 30 watts, instead of 200, and reduce the cost of up-keep to something like 200 units a year instead of 1,600 The primary current going out of the station is then taken through the series coil of the Thomson wattmeter, and in order to keep all the parts of the wattmeter at the same potential one terminal of the secondary circuit and the little transformer is also joined up to the primary main on the side nearest to it. It is usual to mount the transformer and wattmeter on one board, and then to insulate the whole of this board well. The first step is to calibrate the wattmeter. This can be done most easily on a 100-volt circuit by passing through the meter known powers, and observing the reading of the dials. The constant of the meter then has to be multiplied by the transformation ratio of the small transformer, in order to obtain what may be called the high tension constant of the meter. When this is done the meter can be set up in the station in such a way that the whole current going out of the station passes through the meter, and the engineer can, by taking observations from day to-day, record the whole number of units which have been sent out from the generating station on the primary circuits in any interval of time. In exactly the same manner I have found it possible to employ a Mengarini wattmeter coupled with a transformer and placed on the primary circuit. This

Digitized by Google

has the advantage that it not only enables us to record the whole of the energy going out of the station in a given time, but to know at any instant the primary watts.

Before placing confidence in either of these two methods, I made a very careful series of observations on an inductive alternating current primary circuit, in which I employed the Thomson self-integrating wattmeter, as above described, to measure the whole number of units sent out along that primary circuit in four hours, and at the same time observations were made on the same circuit by means of a wattmeter to obtain the power sent out at intervals of minutes. When these observations were compared and reduced, it was found that the power sent out in four hours, as determined by the observations, was 66·924 units in the wattmeter, and the energy given by the self-integrating Thomson wattmeter in the same time was 66·946. It thus became evident that the Thomson recording wattmeter was capable of giving very accurate results as a primary wattmeter, and that there is no reason whatever why the record of the primary energy sent out should not be made in alternating-current stations with the same accuracy as in the case of continuous-current stations.

To complete arrangements it would be desirable, in the case of an alternating-current station, in order to enable the engineer to know exactly what the result of his working is, to act as follows :— On the primary should be placed, in the first place, an ammeter, capable of measuring alternating currents and giving the mean-square value. In the second place, an electrostatic high-tension voltmeter should be connected across the mains in order to give the high-tension volts. In front of this instrument should be placed a Mengarini wattmeter and a Thomson self-recording wattmeter, the whole primary current from the station going through the series coils of these instruments. The shunt circuits of these instruments should be excited by a small transformer, transforming *down from* a working pressure of 100 to 50 volts. These instruments would then enable the engineer, by daily readings, to record, first, the energy sent out of the primary circuits in Board of Trade units in any time ; secondly, the power being sent out at any instant measured in watts ; thirdly, the primary current being sent out at any instant, and the primary pressure, and, therefore, from the product of these two, the apparent power being sent out at any instant ; and fourthly, from the readings of the real and apparent power, the power factor of the station could be ascertained at any instant. By comparing these readings with the sum total of the house meters taken at any intervals, the engineer would be enabled to know the efficiency of distribution of his alternating-current station, and to reckon out, not only the cost of the unit sold. but the cost of the unit generated, and to watch and know the effect of any improvements that are made in the transformers on the system.

It is only by adopting such methods of measurement that engineers in charge of alternating-current stations will be able to remove the reproach which is sometimes hurled at them, that they have no means of measuring the energy or power they are supplying, or of knowing how much of what they make is sold.

MR. R. T. GLAZEBROOK'S PRESIDENTIAL ADDRESS TO SECTION A.

[ABSTRACT.]

Before dealing with the subject which I hope to bring to your notice this morning, I wish to express my deep regret for the circumstances which have prevented Prof. Clifton, who had accepted the nomination of the Council, from being your President this year. It was specially fitting that he who has done so much for this college, and particularly for this laboratory in which we meet, should take the chair at Nottingham. The occasions on which we see him are all too seldom ; and we who come frequently to these meetings were looking forward to help and encouragement in our work, derived from his wide experience. You would desire, I feel sure, that I should convey to him the expressions of your sympathy. For myself I must ask that you will pass a lenient judgment on my efforts to fill his place. Let me commence, then, with a brief retrospect of the past year and the events which concern our Section.

The conference on electrical standards held at our meeting last year has had important results. The resolutions adopted at Edinburgh were communicated to the Standards Committee of the Board of Trade. A supplementary report accepting these resolutions was agreed to by that Committee (November 29, 1892), and presented to the President of the Board of Trade. The definitions contained in this report will be made the basis of legislation throughout the world. They have been accepted by France, Germany, Austria, and Italy. There is good reason to believe that the congress at Chicago now being held will ratify them, and then we may claim that your Committee, co-operating with the leaders of physical science in other lands, has secured international agreement on these fundamental points. Among the physical Papers of the year I would mention a few as specially calling for notice. Mr. E. H. Griffiths's redetermination of the value of the mechanical equivalent of heat has just been published,* and is a monumental work. With untiring energy and great ability he struggled for five years against the difficulties of his task, and has produced results which, with the exception of one group of experiments, do not differ by more than 1 part in 10,000 ; while the results of that one excepted group differ from the mean only by 1 part in 4,000. The number of ergs of work required to raise 1 gramme of water 1°C. at 15°C. is $4{\cdot}194 \times 10^7$. Expressed in foot-pounds and Fahrenheit degrees, the value of J is 778·99. The value obtained by Joule from his experiments on the friction of water, when corrected in 1880 by Rowland so as to reduce his readings to the air thermometer, is 778·5 at 12°·7 C. The result at this temperature of Rowland's own valuable research is 780·1. Another satisfactory outcome of Mr. Griffiths's work is the very exact accordance between the scale of temperature as determined by the comparison of his platinum thermometer with the air thermometer, which was made by Callendar and himself in 1890, and that of the nitrogen thermometer of the Bureau International at Sèvres. Another great work now happily complete is Rowland's "Table of Standard Wavelengths."† Nearly a thousand lines have been measured with the skill and accuracy for which Rowland has made himself famous ; and in this table we see the results achieved by the genius which designed the concave grating and the mechanical ingenuity which contrived the almost perfect screw. Those of us who have seen Mr. Higgs's wonderful photographs of the solar spectrum taken with a Rowland grating will rejoice to know that his map also is now finished. Lord Rayleigh's Paper on "The Intensity of Light Reflected from Water and Mercury at nearly Perpendicular Incidence,"‡ combined with the experiments on reflection from liquid surfaces in the neighbourhood of the polarising angle,§ establishes results of the utmost importance to optical theory. "There is thus," Lord Rayleigh concludes, "no experimental evidence against the rigorous application of Fresnel's formulæ"—for the reflection of polarised light—"to the ideal case of an abrupt transition between two uniform transparent media." Prof. Dewar has, during the year, continued his experiments on the liquefaction of oxygen and nitrogen on a large scale. To a physicist, perhaps, the most important results of the research are the discovery of the magnetic properties of liquid oxygen, and the proof of the fact that the resistance of certain pure metals vanishes at absolute zero.‖ The last discovery is borne out by Griffiths and Callendar's experiments with their platinum thermometers.¶ Mr. Williams's article on "The Relation of the Dimensions of Physical Quantities to Directions in Space"** has led to an interesting discussion. Some of his deductions will be noticed later. The title-page of the first edition of Maxwell's "Electricity and Magnetism" bears the date 1873. This year, (1893) we welcome a third edition, edited by Maxwell's distinguished successor, and enriched by a supplementary volume, in which Prof. J. J. Thomson describes some of the advances made by electrical science in the last twenty years. The subject matter of this volume might well serve as a text for a Presidential Address.

The choice of a subject on which to speak to-day has been no easy task. The field of physics and mathematics is a wide one. There is one matter, however, to which for a few minutes I should like to call your attention, inadequately though it be. Optical theories have, since the year 1876, when I first read Sir George Stokes's "Report on Double Refraction,"†† had a special interest for me, and I think the time has come when we may with advantage review our position with regard to them, and sum up our knowledge.‡‡ That light is propagated by an undulatory motion through a medium which we call the ether is now an established fact, although we know but little of the nature or constitution of the ether. The history of this undulatory theory is full of interest, and has, it appears to me, in its earlier stages been not quite clearly apprehended. Two theories have been proposed to account for optical phenomena. Descartes was the author of the one, the emission theory. Hooke, though his work was very incomplete, was the founder of the undulatory theory. In his "Micrographia,"

‡‡ This address was in the printer's hands when I saw Sir G. Stokes's Paper on "The Luminiferous Ether," *Nature*, July 27th. Had I known that so great a master of my subject had dealt with it so lately, my choice might have been different ; under the circumstances it was too late to change.

Digitized by Google

1664, p. 56, he asserts that light is a quick and short vibratory motion, "propagated every way through an homogeneous medium by direct or straight lines extended every way like rays from the centre of a sphere. . . . Every pulse or vibration of the luminous body will generate a sphere which will continually increase and grow bigger, just after the same manner, though indefinitely swifter, as the waves or rings on the surface do swell into bigger and bigger circles about a point on it;" and he gives on this hypothesis an account of reflexion, refraction, dispersion, and the colours of thin plates. In the same work, p 58, he describes an experiment practically identical with Newton's famous prism experiment, published in 1672. Hooke used for a prism a glass vessel about 2ft. long, filled with water, and inclined so that the sun's rays might enter obliquely at the upper surface and traverse the water. "The top surface is covered by an opaeous body, all but a hole through which the sun's beams are suffered to pass into the water, and are thereby refracted" to the bottom of the glass, "against which part if a paper be expanded on the outside there will appear all the colours of the rainbow—that is, there will be generated the two principal colours, scarlet and blue, with all the intermediate ones which arise from the composition and diluting of these two." But Hooke could make no use of his own observation; he attempted to substantiate from it his own theory of colours, and wrote pure nonsense in the attempt; and though his writings contain the germ of the theory, and in the light of our present knowledge it seems possible that he understood it more thoroughly than his contemporaries believed, yet his reasoning is so utterly vague and unsatisfactory that there is little ground for surprise that he convinced but few of its truth.

And then came Newton. It is claimed for him, and that with justice, that he was the true founder of the emission theory. In Descartes' hands it was a vague hypothesis. Newton deduced from it by rigid reasoning the laws of reflection and refraction; he applied it with wondrous ingenuity to explain the colours of thin and of thick plates and the phenomena of diffraction, though in doing this he had to suppose a mechanism which he must have felt to be almost impossible; a mechanism which in time, as it was applied to explain other and more complex phenomena, became so elaborate that, in the words of Verdet, referring to a period one hundred years later, "all that is necessary to overturn this laborious scaffolding is to look at it and try to understand it."

But though Newton may with justice be called the founder of the emission theory, it is unjust to his memory to state that he accepted it as giving a full and satisfactory account of optics as they were known to him. When he first began his optical work he realised that facts and measurements were needed, and his object was to furnish the facts. He may have known of Hooke's theories. The copy of the "Micrographia" now at Trinity College was in the library while Newton was working with his prism in rooms in college, and may have been consulted by him. An early note-book of his contains quotations from it. Still there was nothing in the theories but hypotheses unsupported by facts, and these would have no charm for Newton. The hypotheses in the main are right. Light is due to wave motion in an all-pervading ether; the principle of interference, vaguely foreshadowed by Hooke ("Micrographia," p. 66), was one which a century later was to remove the one difficulty which Newton felt. For there was one fact which Hooke's theory could not then explain, and till that explanation was given the theory must be rejected; the test was crucial, the answer was decisive. Newton tells us repeatedly what the difficulty was. In reply to a criticism of Hooke's in 1672, he writes: "For to me the fundamental supposition itself seems impossible, namely, that the waves or vibrations of any fluid can, like the rays of light, be propagated in straight lines without continual and very extravagant spreading and bending into the quiescent medium where they are terminated by it. I mistake if there be not both experiment and demonstration to the contrary. . . . For it seems impossible that any of those motions or pressions can be propagated in straight lines without the like spreading every way into the shadowed medium." Nor was there anything in the controversy with Hooke, which took place about 1675, to shake this belief. Hooke had read his Paper describing his discovery of diffraction. He had announced it two years earlier, and there is no doubt in my mind that this was an original discovery, and not, as Newton seemed to imply soon after, taken from Grimaldi; but his Paper does not remove the difficulty. Accordingly, we find in the "Principia" Newton's attempted proof (lib. ii. prop. 42) that "motus omnis per fluidum propagatus divergit a recto tramite in spatia immota"—a demonstration which has convinced but few and leaves the question unsolved as before. Again, in 1690, Huygens published his great "Traité de la Lumière," written in 1678. Huygens had clearer views than Hooke on all he wrote; many of his demonstrations may be given now as completely satisfactory, but on the one crucial matter he was fatally weak. He, rather than Hooke, is the true founder of the undulatory theory, for he showed what it would do if it could but explain the rectilinear propagation. The reasoning of the latter part of Huygens' first chapter becomes forcible enough when viewed in the light of the principle of interference enunciated by Young, November 12, 1801, and developed, independently of Young, by Fresnel in his great memoir on "Diffraction" in 1815; but without this aid it was not possible for Huygen's arguments to convince Newton, and hence in the "Opticks" (Second edition, 1717) he wrote the celebrated Query 28: "Are not all hypotheses erroneous in which light is supposed to consist in pressure or motion propagated through a fluid medium? If it consisted in motion propagated either in an instant or in time it would bend into the shadow. For pressure or motion cannot be propagated in a fluid in right lines beyond an obstacle which stops part of the motion, but will bend and spread every way into the quiescent medium which lies outside the shadow." These were his last words on the subject. They prove that he could not accept the undulatory theory; they do not prove that he believed the emission theory to give the true explanation. Yet, in spite of this, I think that Newton had a clearer view of the undulatory theory than his contemporaries, and saw more fully than they did what that theory could achieve if but the one difficulty were removed. This was Young's belief, who writes:—* "A more extensive examination of Newton's various writings has shown me that he was in reality the first who suggested such a theory as I shall endeavour to maintain: that his own opinions varied less from this theory than is now almost universally believed; and that a variety of arguments have been advanced as if to meet him which may be found in a nearly similar form in his own works." I wish to call attention to this statement, and to bring into more prominent view the grounds on which it rests, to place Newton in his true position as one of the founders of the undulatory theory. The emission theory in Newton's hands was a dynamical theory; he traced the motion of material particles under certain forces, and found their path to coincide with that of a ray of light; and in the "Principia," prop. xcvi, Scholium, he calls attention to the similarity between these particles and light. The particles obey the laws of reflection and refraction; but to explain why some of the incident light was reflected and some refracted Newton had to invent his hypothesis of fits of easy reflection and transmission.

Such was Newton's theory. It accounts for some or all of the observed facts; but what causes the fits? Newton, in the "Opticks," states that he does not inquire; he suggests, for those who wish to deal in hypotheses, that the rays of light striking the bodies set up waves in the reflecting or refracting substance which move faster than the rays and overtake them. When a ray is in that part of a vibration which conspires with its motion it easily breaks through the refracting surface—it is in a fit of easy transmission; and, conversely, when the motion of the ray and the wave are opposed, it is in a fit of easy reflection. But he was not always so cautious. At an earlier date (1675) he sent to Oldenburg, for the Royal Society, an "Hypothesis explaining the Properties of Light;" and we find from the journal book that "these observations so well pleased the society that they ordered Mr. Oldenburg to desire Mr. Newton to permit them to be published." Newton agreed, but asked that publication should be deferred till he had completed the account of some other experiments which ought to precede those he had described. This he never did, and the hypothesis was first printed in Birch's "History of the Royal Society," Vol. III., pp. 247, 262, 272, &c.; it is also given in Brewster's "Life of Newton," Vol. I., App. 2, and in the *Phil. Mag.*, September, 1846, pp. 187-213. "Were I," he writes in this Paper, "to assume an hypothesis, it should be this, if propounded more generally, so as not to assume what light is, further than that it is something or other capable of exciting vibrations of the ether. First, it is to be assumed that there is an ethereal medium, much of the same constitution with air, but far rarer, subtiller, and more strongly elastic. . . . In the second place, it is to be supposed that the ether is a vibrating medium, like air, only the vibrations far more swift and minute; those of air made by a man's ordinary voice succeeding at more than half a foot or a foot distance, but those of ether at a less distance than the hundred-thousandth part of an inch. And as in air, the vibrations are some larger than others, but yet all equally swift . . . so I suppose the ethereal vibrations differ in bigness, but not in swiftness. . . . In the fourth place, therefore, I suppose that light is neither ether nor its vibrating motion, but something of a different kind propagated from lucid bodies. They that will may suppose it an aggregate of various peripatetic qualities. Others may suppose it multitudes of unimaginable small and swift corpuscles of various sizes springing from shining bodies at great distances one after the other, but yet without any sensible interval of time. . . . To avoid dispute, and make this hypothesis general, let every man here take his fancy; only, whatever light be, I would suppose it consists of successive rays differing from one another in contingent circumstances, as bigness, force, or vigour, like as the sands on the shore . . . and further, I would suppose it diverse from the vibrations of the ether. . . . Fifthly, it is to be supposed that light and ether mutu-

Digitized by Google

ally act upon one another." It is from this action that reflection and refraction come about; "æthereal vibrations are, therefore," he continues, "the best means by which such a subtile agent as light can shake the gross particles of solid bodies to heat them. And so, supposing that light, impinging on a refracting or reflecting ethereal superficies puts it into a vibrating motion, that physical superficies being by the perpetual appulse of rays always kept in a vibrating motion, and the ether therein continually expanded and compressed by turns, if a ray of light impinge on it when it is much compressed, I suppose it is then too dense and stiff to let the ray through, and so reflects it; but the rays that impinge on it at other times, when it is either expanded by the interval between two vibrations or not too much compressed and condensed, go through and are refracted. . . . And now to explain colours. I suppose that as bodies excite sounds of various tones, and, consequently, vibrations in the air of various bignesses, so when the rays of light by impinging on the stiff refracting superfices excite vibrations in the ether, these rays excite vibrations of various bignesses . . . the biggest with the strongest colours, reds and yellows; the least with the weakest, blues and violets; the middle with green; and a confusion of all with white." The last idea, the relation of colour to the bigness of wave-length, is put even more plainly in the "Opticks," query 13 (ed. 1704):—"Do not several sorts of rays make vibrations of various bignesses, which according to their bignesses excite sensations of various colours . . . and, particularly, do not the most refrangible rays excite the shortest vibrations for making a sensation of deep violet; the least refrangible, the largest for making a sensation of deep red?"

Thus Newton, while in the "Opticks" he avoided declaring himself as to the mechanism by which the fits of easy reflection and transmission were produced, has in his earlier writings developed a theory practically identical in many respects with modern views, though without saying that he accepted it. It was an hypothesis; one difficulty remained, it would not account for the rectilinear propagation, and it must be rejected till it did. Light is neither ether nor its vibrating motion; it is energy which, emitted from luminous bodies, is carried by wave motion in rays, and falling on a reflecting surface sets up fresh waves, by which it is in part transmitted and in part reflected. Light is not material, but Newton nowhere definitely asserts that it is. He "argues the corporeity of light, but without any absolute positiveness." In the "Principia," writing of his particles, his words are:—"The reflections and refractions of light are not very unlike these attractions. Therefore, because of the analogy which exists between the propagation of rays of light and the motion of bodies, it seemed right to add the following propositions for optical purposes, not at all with any view of discussing the nature of rays (whether they are corporeal or not, but only to determine paths of particles which closely resemble the paths of rays." No doubt Newton's immediate successors interpreted his words as meaning that he believed in the corpuscular theory, conceived, as Herschel says, by Newton, and called by his illustrious name. Men learnt from the "Principia" how to deal with the motion of small particles under definite forces. The laws of wave motion were obscure, and till the days of Young and Fresnel there was no second Newton to explain them. There is truth in Whewell's words ("Inductive Sciences," ii., Chap. X.): "That propositions existed in the 'Principia' which proceeded on this hypothesis was with many ground enough for adopting the doctrine." Young's view, already quoted, appears to me more just; and I see in Newton's hypothesis the first clear indication of the undulatory theory of light, the first statement of its fundamental laws.

Three years later (1678) Huygens wrote his "Traité de la Lumière," published in 1690. He failed to meet the main difficulty of the theory, but in other respects he developed its consequences to a most remarkable degree. For more than a century after this there was no progress, until in 1801 the principle of interference was discovered by Young, and again independently a few years later by Fresnel, whose genius triumphed over the difficulties to which his predecessors had succumbed, and, by combining the principles of interference and transverse vibrations, established an undulatory theory as a fact, thus making Newton's theory a *vera causa*. There is, however, a great distinction between the emission theory as Newton left it and Fresnel's undulatory theory. The former was dynamical, though it could explain but little; the particles of light obeyed the laws of motion, like particles of matter. The undulatory theory of Huygens and Fresnel was geometrical or kinematical; the structure of the ether was and is unknown: all that was needed was that light should be due to the rapid periodic changes of some vector property of a medium capable of transmitting transverse waves. Fresnel, it is true, attempted to give a dynamical account of double refraction, and of the reflection and refraction of polarised light, but the attempt was a failure; and not the least interesting part of Mr. L. Fletcher's recent book on double refraction ("The Optical Indicatrix") is that in which he shows that Fresnel himself in the first instance arrived at his theory by purely geometrical reasoning, and only attempted at a later date to give it its dynamical form. "If we reflect," says Stokes,* "on the state of the subject as Fresnel found it and as he left it, the wonder is, not that he failed to give a rigorous dynamical theory, but that a single mind was capable of effecting so much." Every student of optics should read Fresnel's great memoirs.

But the time was coming when the attempt to construct a dynamical theory of light could be made. Navier, in 1821, gave the first mathematical theory of elasticity. He limited himself to isotropic bodies, and worked on Boscovitch's hypothesis as to the constitution of matter. Poisson followed on the same lines, and the next year (1822) Cauchy wrote his first memoir on elasticity. The phenomena of light afforded a means of testing this theory of elasticity, and, accordingly, the first mechanical conception of the ether was that of Cauchy and Neumann, who conceived it to consist of distinct hard particles acting upon one another with forces in the line joining them, which vary as some function of the distance between the particles. It was now possible to work out a mechanical theory of light which should be a necessary consequence of these hypotheses. Cauchy's and the earlier theories do not represent the facts either in an elastic solid or in the ether. At present we are not concerned with the cause of this; we must recognise it as the first attempt to explain on a mechanical basis the phenomena observed. According to his theory in its final form, there are, in an isotropic medium, two waves which travel with velocities $\sqrt{A/\rho}$ and $\sqrt{B/\rho}$, A and B being constants, and ρ the density. Adopting Cauchy's molecular hypothesis, there must be a definite relation between A and B. A truer view of the theory of elasticity is given by Green in his Paper read before the Cambridge Philosophical Society in 1837. This theory involves the two constants, but they are independent, and to account for certain optical effects A must either vanish or be infinite. The first supposition was, until a few years since, thought to be inconsistent with stability; the second leads to consequences which in part agree with the results of optical experiment, but which differ fatally from those results on other points. And so the first attempt to construct a mechanical theory of light failed. We have learnt much from it. At the death of Green the subject had advanced far beyond the point at which Fresnel left it. The causes of the failure are known, and the directions in which to look for modifications have been pointed out.

Now I believe that the effort to throw any theory into mechanical form, to conceive a model which is a concrete representation of the truth, to arrive at that which underlies our mathematical equations wherever possible, is of immense value to every student. Such a course, I am well aware, has its dangers. It may be thought that we ascribe to the reality all the properties of the model, that, in the case of the ether, we look upon it as a collection of gyrostatic molecules and springs, or of pulleys and india-rubber bands, instead of viewing it from the standpoint of Maxwell, who hoped, writing of his own model, "that by such mechanical fictions, anyone who understands the provisional and temporary character of his hypothesis will find himself helped rather than hindered in his search after the true interpretation of the phenomena." Prof. Boltzmann, in his most interesting Paper on "The Methods of Theoretical Physics,"† has quoted these words, and has expressed far more ably than I can hope to do the idea I wish to convey.

The elastic solid theory, then, has failed, but are we therefore without any mechanical theory of light? Are we again reduced to merely writing down our equations, and calling some quantity which appears in them the amplitude of the light vibration, and the square of that quantity the intensity of the light? Or can we take a further step? Let us inquire what the properties of the ether must be which will lead us by strict reasoning to those equations which we know represent the laws of the propagation of light. These equations resemble in many respects those of an elastic solid; let us, then, for a moment identify the displacement in a light wave with an actual displacement of a molecule of some medium having properties resembling that of a solid. Then this medium must have rigidity or quasi-rigidity in order that it may transmit transverse waves; at the same time it must be incapable of transmitting normal waves, and this involves the supposition that the quantity A which appears in Green's equations must vanish or be infinite. To suppose it infinite is to recur to the incompressible solid theory; we will assume, therefore, that it is zero. Reflection and refraction show us that the ether, in a transparent medium such as glass, differs in properties from that in air. It may differ either (1) in density or effective density,‡ or (2) in rigidity or effective rigidity.

* "Report on Double Refraction," *Brit. Assoc. Report*, 1862, p. 254.

† *Phil. Mag.*, July, 1893.

‡ The equations of motion for a medium such as is supposed above can be written:

$\rho \times$ acceleration of ether $+ \rho' \times$ acceleration of matter $= \Sigma B \times$ function of ether displacements, and their differential coefficients with respect to the co-ordinates $+ \Sigma B' \times$ similar function for matter displacements.

The quantity ρ may be spoken of as the effective ether density, the quantities B as the effective elasticity or rigidity.

Digitized by Google

The laws of double refraction and the phenomena of the scattering of light by small particles show us that the difference is, in the main, in density or effective density; the rigidity of the ether does not greatly vary in different media. Dispersion, absorption, and anomalous dispersion all tell us that in some cases energy is absorbed from the light vibrations by the matter through which they pass, or, to be more general, by something very intimately connected with the matter. We do not know sufficient to say what that action must be; we can, however, try the consequences of various hypotheses. Guided by the analogy of the motion of a solid in a fluid, let us assume that the action is proportional to the acceleration of the ether particles relative to the matter; and, further, that under certain circumstances, some of the energy of the ether particles is transferred to the matter, thus setting them in vibration. If such action be assumed, the actual density of the ether may be the same in all media; the mathematical expression for the forces will lead to the same equations as those we obtain by supposing that there is a variation of density; and since it is clearly reasonable to suppose that this action between matter and ether is, in a crystal, a function of the direction of vibration, the apparent or effective density of the ether in such a body will depend on the direction of displacement. Now these hypotheses will conduct us by strict mathematical reasoning to laws for the propagation, reflexion, and refraction, double refraction and polarisation, dispersion, absorption, and anomalous dispersion and aberration of light which are in complete accordance with the most accurate experiments. The rotatory polarisation of quartz, sugar, and other substances points to a more complicated action between the ether and matter than is contemplated above; and, accordingly, other terms have to be introduced into the equations to account for these effects. It will be noted as a defect, and perhaps a fatal one, that the connection between electricity and light is not hinted at, but I hope to return to that point shortly.

Such a medium as I have described is afforded us by the labile ether of Lord Kelvin. It is an elastic solid or quasi-solid incapable of transmitting normal waves. The quantity A is zero, but Lord Kelvin has shown that the medium would still be stable provided its boundaries are fixed, or, which comes to the same thing, provided it extends to infinity. Such a medium would collapse if it were not held fixed at its boundaries; but if it be held fixed, and if then all points on any closed spherical surface in the medium receive a small normal displacement, so that the matter within the surface is compressed into a smaller volume, there will be no tendency either to aid or to prevent this compression, the medium in its new state will still be in equilibrium, the stresses in any portion of it which remains unaltered in shape are independent of its volume, and are functions only of the rigidity and, implicitly, of the forces which hold the boundary of the whole medium fixed. A soap film affords in two dimensions an illustration of such a medium; the tension at any point of the film does not depend on the dimensions; we may suppose the film altered in area in any way we please—so long as it remains continuous—without changing the tension. Waves of displacement parallel to the surface of the film would not be transmitted. But such a film, in consequence of its tension, has an apparent rigidity for displacements normal to its surface: it can transmit transverse waves with a velocity which depends on the tension. Now the labile ether is a medium which has, in three dimensions, characteristics resembling those of the two-dimensional film. Its fundamental property is that the potential energy per unit volume, in an isotropic body, so far as it arises from a given strain, is proportional to the square of the resultant twist. In an incompressible elastic ether, this potential energy depends upon the shearing strain. Given such a medium—and there is nothing impossible in its conception—the main phenomena of light follow as a necessary consequence. We have a mechanical theory, by the aid of which we can explain the phenomena; we can go a few steps behind the symbols we use in our mathematical processes. Lord Kelvin, again, has shown us how such a medium might be made up of molecules having rotation in such a way that it could not be distinguished from an ordinary fluid in respect to any irrotational motion; it would, however, resist rotational movements with a force proportional to the twist, just the force required; the medium has no real rigidity, but only a quasi-rigidity conferred on it by its rotational motion. The actual periodic displacements of such a medium may constitute light. We may claim, then, with some confidence, to have a mechanical theory of light.

But nowadays the ether has other functions to perform, and there is another theory to consider, which at present holds the field. Maxwell's equations of the electromagnetic field are practically identical with those of the quasi-labile ether. The symbols which occur can have an electromagnetic meaning; we speak of permeability and inductive capacity instead of rigidity and density, and take as our variables the electric or magnetic displacements instead of the actual displacement or the rotation. Still, such a theory is not mechanical. Electric force acts on matter charged with electricity, and the ratio of the force to the charge can be measured in mechanical units. A fundamental conception in Maxwell's theory is electric displacement, and this is proportional to the electric force. Moreover, its convergence measures the quantity of electricity present per unit volume; but we have no certain mechanical conception of electric displacement or quantity of electricity, we have no satisfactory mechanical theory of the electromagnetic field. The first edition of "Electricity and Magnetism" appeared twenty years ago. In it Maxwell says: "It must be carefully borne in mind that we have made only one step in the theory of the action of the medium. We have supposed it to be in a state of stress, but we have not in any way accounted for this stress or explained how it is maintained. This step, however, appears to me to be an important one, as it explains by the action of consecutive parts of the medium phenomena which were formerly supposed to be explicable only by direct action at a distance. I have not been able to make the next step, namely, to account by mechanical considerations for these stresses in the dielectric." And these words are true still. But for all this, I think it may be useful to press the theory of the quasi-labile ether as far as it will go, and endeavour to see what the consequences must be.

The analogy between the equations of the electromagnetic field and those of an elastic solid has been discussed by many writers. In a most interesting Paper on the theory of dimensions, read recently before the Physical Society, Mr. Williams has called attention to the fact that two only of these analogies have throughout a simple mechanical interpretation. These two have been developed at some length by Mr. Heaviside in his Paper in *The Electrician* for January 23, 1891. To one of them Lord Kelvin had previously called attention ("Collected Papers," Vol. III., p. 450). Starting with a quasi-labile ether, then, we may suppose that μ, the magnetic permeability of the medium, is $4\pi\rho^*$, where ρ is the density, and that K, the inductive capacity, is $1/4\pi B$, B being the rigidity, or the quasi-rigidity conferred by the rotation.

The kinetic energy of such a medium is $\frac{1}{2}\rho(\dot{\xi}^2+\dot{\eta}^2+\dot{\zeta}^2)$, where $\dot{\xi}$, $\dot{\eta}$, $\dot{\zeta}$ are the components of the displacement. Let us identify this with the electromagnetic energy $(\alpha^2+\beta^2+\gamma^2)8\pi$, α, β, γ being components of the magnetic force, so that $\alpha=\dot{\xi}$, $\beta=\eta$, $\gamma=\zeta$. Then the components of the electric displacement, assuming them to be zero initially, are given by

$$f=\frac{1}{4\pi}\left(\frac{d\dot{\zeta}}{dy}-\frac{d\dot{\eta}}{dz}\right), \text{ \&c.;}$$

that is, the electric displacement $\mathfrak{D}$ multiplied by 4π is equal to the rotation in the medium. Denote this by Ω.

The potential energy due to the strain is

$$\tfrac{1}{2}B\Omega^2, \text{ or } \tfrac{1}{2}16\pi^2 B\mathfrak{D}^2,$$

and on substituting for B this becomes

$$\frac{1}{2}\frac{4\pi}{K}\mathfrak{D}^2,$$

which is Maxwell's expression for the electrostatic energy of the field.

Thus, so far, but no farther, the analogy is complete; the kinetic energy of the medium measures the magnetic energy, the potential energy measures the electrostatic energy. The stresses in the ether, however, are not those given by Maxwell's theory. In the other form of the analogy we are to take the inductive capacity as $4\pi\rho$ and the magnetic permeability as $1/4\pi B$. The velocity measures the electric force, and the rotation the magnetic force, so that electrostatic energy is kinetic, and magnetic energy potential. Such an arrangement is not so easy to grasp as the other. Optical experiments, however, show us that in all probability it is ρ, and not B, which varies, while from our electrical measurements we know that K is variable and μ constant; hence this is a reason for adopting the second form. In either case we look upon the field as the seat of energy distributed per unit of volume according to Maxwell's law. The total energy is obtained by integration throughout the field. Now, we can transform this integral by Green's theorem to a surface integral over the boundary, together with a volume integral through the space; and the form of these integrals shows us that we may look upon the effects, dealing for the present with electrostatics only, as due to the attractions and repulsions of a certain imaginary matter distributed according to a definite law over the boundary and throughout the space. To this imaginary matter, then, in the ordinary theory we give the name of Electricity. Thus an electrified conducting sphere, according to these analogies, is not a body charged with a quantity of something we call electricity, but a surface at which there is a discontinuity in the rotation impressed upon the medium, or in the flow across the surface, for in the conductor a viscous resistance to the motion takes the place of rigidity. No permanent strain can be set up.

From this standpoint we consider electrical force as one of the manifestations of some action between ether and matter. There are certain means by which we can strain the ether: the friction of two

* If we adopted Mr. Heaviside's rational system of units, the 4π would disappear.

Digitized by Google

dissimilar materials, the chemical action in a cell are two; and *when, adopting* the first analogy, this straining is of such a nature as *to produce* a rotational twist in the ether, the bodies round are said to be *electrified*; the energy of the system is that which would arise from the presence over their surfaces of attracting and repelling matter, attracting or repelling according to the inverse square law. We falsely assign this energy to such attractions instead of to the strains and stresses in the ether. Such a theory has many difficulties. It is far from being proved; perhaps I have erred in trespassing on your time with it in this crude form. The words of the French *savant*, quoted by Poincaré, will apply to it: "I can understand all Maxwell except what he means by a charged body." It is not, of course, the only hypothesis which might be formed to explain the facts, perhaps not even the most probable. For many points the vortex sponge theory is its superior. Still, I feel confident that in time we shall come to see that the phenomena of the electromagnetic field may be represented by some such mechanism as has been outlined, and that confidence must be my excuse for having ventured to call your attention to the subject.

ELECTRICAL ACTION OF LIGHT UPON SILVER.*

BY COL. J. WATERHOUSE.

More than half a century ago, in 1839, Edmond Becquerel was the first to show that the electrical action accompanying the chemical changes brought about by the influence of light upon various substances, including the silver haloids, could be observed with a delicate galvanometer. He found that this action was quite independent of any heating of one electrode more than another, but was powerfully affected by the different rays of the spectrum, the greatest action being produced by the violet, indigo and blue rays, while with the green, yellow and red rays there was little or no action. To observe these effects he used a covered vessel divided into two parts by a thin membrane. In each of the compartments he placed a plate of platinum or gold, previously made red-hot to remove all impurities, the plates being connected with the poles of a very sensitive galvanometer, and laid horizontally in the apparatus. Each compartment had a movable cover. He found that when the two compartments contained an alkaline solution, the plate exposed to the solar rays took negative electricity, while the reverse occurred if the solution were acid. When two silver plates were immersed in water acidulated with nitric acid exposure to light of one plate only produced a very weak current and the exposed plate was always positive. He found that when silver halide, precipitated in a thin layer on sheets of platinum or gold, was exposed to light, the exposed plate was positive, and that the initial action was much stronger with the bromide than with the chloride. With the iodide the current was almost as strong as with the chloride, but did not remain constant so long. When plates of silver were employed, instead of platinum or gold, as a support for the haloids, the effects noted were stronger and more regular, but it was found that the direction of the current depended on the thickness of the films; with thin coatings the exposed plate was positive, and with thick coatings negative. On the basis of these experiments Becquerel invented his electro-chemical actinometer, which was practically a voltaic element or cell composed of two plates of very pare silver coated with the violet subchloride of silver and plunged into a conducting fluid composed of two parts of monohydrated sulphuric acid in 100 parts of water. When diffused daylight or sunshine acted upon one of the plates, more or less deviation of the needle was observed which remained constant so long as the light remained of the same intensity and the surface was sufficiently sensitive. If the light was shut off, the needle returned to zero or somewhat beyond it, but soon regained its original position. The deflections of the needle could not, however, be considered as proportional to the intensity of the chemical action.

At the meeting of the British Association in 1880, Prof. G. M. Minchin gave an account of his experiments on the generation of electric currents by the action of light on silver plates which were coated with emulsions of bromide, chloride, iodide, and other salts of silver in gelatine and collodion, as well as with eosine, fluorescine, and various aniline dyes, the object of these experiments being the solution of the problem of producing a photographic image of an object at a distance. He found that when two pieces of clean silver foil attached to glass plates were coated with an emulsion of chloride of silver in collodion, and immersed in distilled water containing a few grains of common salt, the plates being connected with the terminals of a Thomson's galvanometer, and one of them screened from the light, that on exposing the unscreened plate there was an electric current produced, and the exposed plate was *negative* to the unexposed. When the plates were coated with iodide of silver in collodion by the wet silver-bath method, the liquid being water containing a little potassium iodide, there was a reversal of the nature of the exposed plate, it being *positive* to the unexposed.

In carrying out my experiments I have used two kinds of cells, one horizontal and one vertical, more usually the latter. It consists of a glass cell in which the plates can be coupled face to face or back to back, one being screened from light by the other and by one or two interposed screens of ruby or yellow glass, the cell being covered all round except at an opening on one side. This glass cell is enclosed in a wooden box with a shutter on one side sliding in front of an opening about 1·5in. × 0 5in., corresponding to the one in the glass cell. In front of this shutter there are grooves in which coloured glasses can be placed in front of the opening. The upper part of the wooden case is open, but can be closed by a lid, through which, if necessary, a funnel may be passed to admit of solutions being poured into the cell without letting in light.

As a rule my observations with coloured glasses or the spectrum have agreed with Becquerel's and Minchin's, that no reversal of sign is produced by any of the coloured rays. At the same time, I have found that in some cases the blue rays appear to have a reversing tendency, as might be anticipated from their very strong reversing action on certain forms of sensitive photographic plates containing iodide or bromo-iodide of silver.

The action of dilute sulphuric acid upon silver plates under the influence of light seems to be rather irregular, but I find that in nearly all cases the first exposed plate of each pair had a negative tendency when first exposed, though it might become positive by subsequent exposures, and in the same way the second plate of the pair, which was screened during the first exposure, might also be positive on first exposure. The general tendency was undoubtedly positive. In one experiment, however, the exposed plate was distinctly and uniformly negative, even after the position of the plates had been reversed, but subsequent exposure of the reversed plate made it positive. In another it was negative on first exposure and then positive.

With nitric acid the exposed plates are nearly always positive, and the action is far more uniform than with sulphuric acid. With distilled water acidified with about one drop of acid in 70cc., the exposed plate was positive on first exposure, but afterwards became negative. With dilute phosphoric acid the deflections were almost always positive. With 1 per cent. of hydrochloric acid, *sp. g.* 1·150, in distilled water, the exposed plates have shown themselves uniformly positive, and owing to the formation of a deposit of chloride they are much more sensitive to light. With dilute hydrobromic acid containing 10cc. of the ordinary dilute acid to 100cc. distilled water, the plate exposed to sunshine or diffused daylight was uniformly *negative* and extremely sensitive to light.

With a solution of 1 per cent. of caustic potash in distilled water, exposure to bright sunshine gave a deflection, the exposed plate being positive.

* Abstract *Journal* Asiatic Society of Bengal. Vol. LXII., Part II., No. 1, 1893.

ADDENDUM TO NOTE ON THE NATURE OF DEPOLARISERS.*

BY PROF. HENRY E. ARMSTRONG.

I am induced to somewhat extend my recent note† on depolarisers in order that the argument there made use of in considering the dissolution of metals such as magnesium in nitric acid may be clearly understood and its consequences more fully realised.

It is one of the most noteworthy features of such interactions that when reduction is carried beyond the nitric oxide stage, it invariably proceeds to ammonia, and gives rise to a variety of products; so that whereas neither nitrous oxide nor nitrogen is evolved when metals such as silver and mercury are dissolved, these two gases are always obtained when more active metals are the agents. From this it would appear that there is a limit of (?) E.M.F. which must be exceeded if it be desired to extend the reduction beyond the stage involving the formation merely of nitrogen dioxide and monoxide.

A somewhat similar case is presented by the behaviour of sulphuric acid solutions on electrolysis. Whereas, under certain conditions, besides hydrogen, only oxygen is obtained, under others ozone, persulphuric acid and hydrogen peroxide are also produced. This apparently is a phenomenon of the same order, but in a measure the converse of that presented by nitric acid, as oxygen—not hydrogen—is the active substance. Judging from McLeod's observations (*C.S. Trans.*, 1886, 591), it is clear that "current

Digitized by Google

density" is an all-important factor in determining "peroxidation," but it remains to be determined whether it is the sole factor. The individual influence of E.M.F., of current strength and of current density; in fact, all require careful study in this as in many other cases of electrolysis; undoubtedly much depends on the concentration of the acid. The peroxidation may be regarded as the outcome of oxygen depolarisation, effected apparently in two ways; part of the oxygen becoming affixed to sulphuric acid, persulphuric acid is formed, which in part gradually undergoes hydrolysis, affording hydrogen peroxide—a non-electrolytic change; while another part serves as oxygen depolariser, affording ozone. On this assumption, ozone is not the product of the fortuitous concourse of three oxygen atoms but of the interaction of oxygen atoms in circuit with persulphuric acid; and if this be the origin of electrolytic ozone, it appears not improbable that the oxidation of phosphorus, which is attended by the formation of ozone, will also be found to involve the formation of a peroxide hitherto undiscovered.

In the case of a metal such as magnesium dissolving in considerable excess of nitric acid, if a plate be imagined to be undergoing attack and conversion into nitrate at any one point, the displaced hydrogen may, it would seem, "travel along" a very large number of paths to other points on the plate capable of acting as negative pole and of there meeting with nitric acid in sufficient amount to oxidise it; and it is scarcely conceivable, therefore, that it should escape if the nitric acid act directly as depolariser. It is also difficult to understand why one substance, an electrolyte, should act in two ways in the same circuit, and the difficulty appears to be equally great whether any form of Grothus's hypothesis, or a dissociation hypothesis, be adopted in explanation of electrolysis. But these difficulties seemingly disappear if—as previously suggested—the active depolariser be a nitrous compound or derivative; perhaps, at all events, at the initial stage, nitrogen dioxide. Moreover, it would appear to be possible in this manner to account also for the extension of the reduction to ammonia; in the case of a metal like silver the amount of depolariser must always tend to reach a maximum value depending on the extent to which the reversible interchange expressed by the equation $NO+2HNO_3=3NO_2+OH_2$, is limited by the concentration and temperature; but it is limited by these conditions alone. In the case of more active metals, it appears probable that the nitric oxide also functions as depolariser, and is reduced to hydroxylamine and ultimately to ammonia. If such an action take place, it follows (from Ohm's law) that the more active the metal the more rapidly will hydrogen be displaced by it, giving greater opportunity, therefore, for nitric oxide to undergo reduction and leading to the production of an increased proportion of products of extended reduction. Any circumstance which would tend to diminish the proportion of nitrogen dioxide relatively to monoxide present in solution would, therefore, promote the formation of such products, and, in point of fact, Acworth and I have noticed, even in the case of copper, that when the metal is dissolved in diluted nitric acid, it appears to be more "active," *i.e.*, to furnish a larger proportion of products of extended reduction, than when more concentrated acid is used: as the presence of water must obviously favour the reversal of the interchange expressed by the equation $NO+2HNO_3=3NO_2+H_2O$, so that weaker would potentially contain a larger proportion of monoxide than stronger solutions of nitric acid, these observations would appear to be in harmony with the hypothesis here advocated. There is no evidence, be it remarked, that hyponitrous acid can be formed in acid solution, *i.e.*, by direct reduction of nitric or even of nitrous acid, and the whole of the nitrous oxide which is evolved when metals are disolved in nitric acid may result from the interaction of nitrous acid and hydroxylamine. That reduction invariably extends to ammonia whenever hydroxylamine is formed is probably a consequence of the extreme readiness with which hydroxylamine is itself reduced, so that, in fact, when reduction once proceeds beyond the nitric oxide stage, it is to be supposed that there are necessarily a number of competing depolarisers present in solution—nitrogen dioxide and monoxide and hydroxylamine (and perhaps others), none of which, however, are electrolytes in the sense in which the term is ordinarily understood. And here it may be pointed out that the fact that a nitrate may be reduced in alkaline solution by sodium amalgam, or aluminium, or zinc is no argument against the conclusion above arrived at, that probably nitric acid does not directly act as depolariser, as in these cases the alkaline solution appears to be the electrolyte, and the nitrate merely the depolariser—so that the nitrate does not act in two ways. As nitrates may be wholly converted into ammonia by reducing an alkaline solution, it would seem probable that in such cases hydroxylamine is not an intermediate product, as nitrogen is obtained on boiling an alkaline solution of this substance.

The argument here made use of would appear also to afford an explanation of the effect produced by varying the E.M.F., *i.e.* by metals of different degrees of "activity"; as increase of E.M.F., other conditions remaining unchanged, would increase the current strength and consequently the rate of change; and, as indicated above, an increase in the rate of change would doubtless involve an increase in the amount of products of extended reduction.

It remains to be pointed out that the objection made to the assumption that nitric acid can act in two ways is equally applicable to the case of sulphuric acid; in other words, that it is not likely that sulphuric acid would act as electrolyte and as oxygen depolariser. It becomes necessary, therefore, to reconsider the manner in which solutions of this acid undergo electrolysis. On the one hand it is conceivable that the water molecule alone suffers partition, not the sulphuric acid (H_2SO_4) molecule, as commonly supposed, and that under certain conditions the latter takes a direct part in the change, becoming oxidised; but this does not appear to be probable, especially as there is reason to believe that the acid in conjunction with water actually functions as electrolyte. An alternative assumption would be that the immediate product has been overlooked, and it can scarcely be gainsaid that there is much evidence in favour of this view. It is not improbable that the first products of electrolysis are hydrogen and *persulphuric* acid; it may be supposed that under "ordinary" circumstances this latter substance is resolved at the electrode surface into oxygen and sulphuric acid, but when the electrode surface is small much escapes unchanged, this being especially the case when the electrolyte is a somewhat concentrated acid—a condition which in itself favours the survival of persulphuric acid. Not only do recent observations on the electrolysis of various sulphates support this contention, but it would seemingly also serve to explain the extraordinary character of the curve representing the change in conductivity of solutions of sulphuric acid on dilution.

THE BRUSH-ADAMS ARC LAMP CLUTCH.*

Surrounding the Brush exhibit in Electricity Building at Chicago is a line of double carbon arc lamps whose steady burning is generally remarked. These lamps, though employing the clutch principle, so successfully applied by Brush, have a somewhat different arrangement for releasing the carbon from that originally employed. In the original form Brush, it will be remembered, employed the simple ring or washer, which encircled the carbon rod and the tilting of which, under the action of the magnets, allowed the carbon to feed, or held it in position. The lamps at present manufactured by the Brush Company, however, have a modified clutch arrangement, the joint invention of Mr. Brush and Mr. T. E. Adams, superintendent of the Brush lamp department. A glance at the accompanying illustrations will make clear the new arrangement.

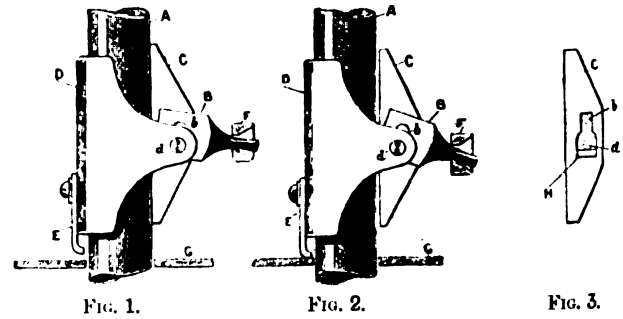

Fig. 1. Fig. 2. Fig. 3.

New Form of Clutch for Brush Arc Lamp.

Instead of the ring, a saddle, D, is employed, which is pressed against the rod by a shoe, C, both loosely pivotted in the clutch-lever B, which is acted by the arm F, which represents the end of the armature controlled by the regulating lamp magnets. Fig. 1 shows the position of the rods where the arc is sprung. As soon as the carbons burn away the weakening of the regulating magnets allows the armature, F, to drop, as shown (somewhat exaggerated) in Fig. 2, and releases the lamp rod just sufficiently to allow it to fall a slight amount; but just as soon as it reaches the point where the arc is of normal length the magnets are again energised and the clutch is applied, but at a point a little above its former position, where it is maintained until the carbons require readjustment.

The action of the clutch is imperceptible, and the feeding cannot be observed while the lamp is burning.

* From the *Electrical Engineer* of New York.

A Temporary Telegraph Line.—A temporary line of telegraph will be run up from Jamrud to Lundi-Kotal to facilitate communication with Kabul during the stay of the Durand mission in Afghanistan.

CORRESPONDENCE.

THE NEW (?) INCANDESCENT ARC LAMP.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I observe in your journal, as well as in the other technical papers, a description of "an improved arc light," which was described in a Paper read at Chicago by Mr. Marks. I always think it rather hard to see a device brought out as new which has already been carried out by oneself. In 1882 the very same lamp there spoken of I made and used, and only dropped the matter, finding that there was no great advantage to be gained, compared with little troubles which followed the new arrangement. To avoid the difficulties of passing the carbons through a closed globe I employed a Jablochkoff candle. The apparatus was made for me by Messrs. Baker, of Holborn, and finished off here, so that ample evidence exists of the facts I mention.—Yours, &c., DAVID L. SALOMONS.

Broomhill, Tunbridge Wells, Sept. 9, 1893.

TRADE NOTES AND NOTICES.

[Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.]

The 1893 Edition of "THE ELECTRICIAN" Electrical Trades' Directory and Handbook contains over 1,000 pages, several new and handy features having been added. Price 7s. 6d., post free 8s. 3d.; abroad 8s. 10d. *Comparison with any similar electrical publication is specially invited.*

The 1894 Edition is in preparation, and will be published, as usual, in January. New names, alterations of addresses, &c., are received at any time, but the Directory blanks and circulars are not sent out until later in the year, in order that the most recent, and consequently the *correct*, **addresses** *only* **shall appear in the book.**

TENDERS INVITED.—The Secretary of State for Foreign Affairs has received from Her Majesty's Ambassador at Madrid a copy of a Spanish Royal Order setting forth the conditions for the construction and laying of submarine telegraph cables uniting the islands of Luzon and Las Visayas, tenders for which are invited. The order can be seen on personal application at the Commercial Department of the Foreign Office between the hours of 11 and 6 daily.

——— The St. Pancras Vestry invite tenders for the extension of the buildings at their electric lighting station in Longford-street, which tenders must reach the Vestry Clerk by the 21st instant.

——— The Guardians of the Bristol Incorporation invite tenders for an electric light installation for certain portions of St. Peter's Hospital. Tenders must be in by the 21st inst.

——— The Gas Committee of the Leicester Corporation require tenders for the supply and erection of iron roofing for the electric lighting central station. Tenders must be in by the 23rd inst.

TENDERS RECEIVED.—Tenders have been received by the Bury Town Council from the following firms for the supply of the electric light plant for the central station:—Messrs. Mather and Platt (Limited), Manchester; Messrs. Laing, Wharton and Down, London; Messrs. C. A. Parsons and Co., Newcastle-on-Tyne; Manchester Edison-Swan Company, Manchester; Messrs. Johnson and Philips, Kent; Messrs. Siemens Bros. and Co. (Limited), London; India-Rubber, Gutta-Percha, and Telegraph Works Company (Limited), London and Silvertown; Woodhouse and Rawson (Limited), Manchester; Crompton and Co. (Limited), London; Brush Electrical Engineering Company (Limited), London; Messrs. J. H. Holmes and Co., Newcastle-on-Tyne; John Fowler and Co., Leeds (Limited).

TENDERS ACCEPTED.—The Dawlish Local Board have accepted the tender of Mr. James, of Exeter, to fit electric call bells to the houses of the firemen. A tender was also received from the National Telephone Company.

SALES BY AUCTION.—We would remind our readers that the sale by auction by Messrs. Furber, Price and Furber, of the valuable plant, machinery, and instruments of the London College of Electrical Engineering will take place on Tuesday and Wednesday next. Some further particulars will be found in our advertisement columns.

——— Mr. J. C. Stevens announces in our advertisement columns that he will sell by auction at 80 and 81, Turnmill-street, E.C., on Thursday next, the 21st inst., the manufacturing machinery and plant of the London Metallurgical Company (Limited).

FACTORY PREMISES TO LET.—Mr. R. A. Came, of 27, Mecklenburgh-square, W.C., has to let commodious factory premises in London.

PERSONAL.—Mr. Robert T. Turnbull requests us to announce that he resigned his position with the New Zealand Electrical Syndicate (Limited) and with the Gülcher (New) Electric Light and Power Company (Limited) on August 17th, and that he is now in business as a consulting electrical engineer at Custom House Quay, Wellington, New Zealand.

——— Mr. Horatio Bell, lately assistant engineer in the Glasgow district of the National Telephone Company, has been appointed engineer and manager of the Greenock district.

CHANGE OF ADDRESS.—Messrs. Babcock and Wilcox (Limited), notify that their address is now 127, Queen Victoria-street, E.C. instead of 114, Newgate-street, as formerly.

MESSRS. DORMAN AND SMITH.—Owing to increasing demand for their special manufactures, Messrs. Dorman and Smith are taking advantage of the termination of an existing agreement to place their London branch under the control of Mr. A. H. Dorman, who, in addition to attending to the London business, proposes to make periodical visits to the chief centres of the electrical industry, especially keeping in touch with the head office and works at Manchester.

LIQUIDATIONS.—At meetings of Abell's Electrical Engineering Company (Limited), held on August 14th and September 1st, resolutions were passed and confirmed that the Company be voluntarily wound up, and that Mr. F. W. Marsh, of Liverpool and St. Helen's, chartered accountant, be liquidator.

———The Registrar has appointed September 18th, at his chambers, Bankruptcy-buildings, Carey-street, W.C., for consideration of the determinations of the meetings of creditors and contributories of the London Metallurgical Company (Limited).

——— A meeting of the Automatic Standard Screw Company (Limited) will be held at Mr. T. England's, Town Hall-chambers, Crossley-street, Halifax, on October 13th, at 4 p.m., to receive an account of the winding-up.

——— Meetings of the creditors and shareholders of the International Electric Syndicate (Limited) were held on Wednesday, and, no resolutions being passed, the liquidation proceedings were left in the hands of the Official Receiver. Mr. Cully, assistant-receiver, stated that the Company was promoted in April, 1891, by Mr. Robert Williams Davey, who had absconded, and against whom bankruptcy proceedings were instituted last December. It appeared beyond doubt that there had been a considerable amount of fraud in connection with the Company's promotion. The patents acquired by the Company had not been traced, and a question would arise as to the proper ownership, as one of the vendors had repudiated the shares issued to him as consideration, and claimed a return of the patents. The attempts to trace Mr. Davey had also proved abortive, and, in his absence, no further steps could yet be taken.

BANKRUPTCY.—Selina Phillipine Annie Rowbottom, trading as S. Rowbottom and Co., electrical engineers, at 82, Abbey-street, Derby, has been adjudicated a bankrupt. The first meeting of creditors will be held at the Official Receiver's, Derby, on September 20th, at 12, and the public examination is fixed for October 11th at 2, at the County Hall, Derby.

LINE MATERIAL AND TRACTION APPLIANCES.—Mr. R. W. Blackwell, who is agent for Messrs. A. and J. M. Anderson, forwards us a comprehensive catalogue and price list of the "Anderson" line material and special appliances for electric tramways. The pamphlet deals with insulators, bracket arm hangers, single and double curve pull-offs, terminals, clamps, clips, ears, trolly pulleys and wheels, trolly bases, lightning arresters, wire stretching machines, &c., all of which are fully illustrated.

CHIMATTO ENAMEL.—We have received from Messrs. Fletcher, Russell and Co., of Warrington, a small cast iron gas boiler, the surface of which has been treated with "chimatto enamel." This process permits of an iron surface being given all manner of deli-

Digitized by Google

cate tints, and is a decided improvement upon the shiny coating of Brunswick black which we usually associate with domestic iron work.

WRAY ELECTRICAL ENGINEERING COMPANY.—This Company have secured the contract for the erection of an electric light plant at the extensive cotton mills of Messrs. E. Heyworth and Son, Blackburn. The installation will consist of about 750 16-c.p. lamps, with separate slow speed vertical Robey engine, in combination with a direct-driven dynamo. The firm are also engaged on the wiring and fitting of the Mersey Rice and Flour Mill, Liverpool. This will be one of the largest electric light installations in corn mills in the North, and will consist of two 400-light dynamos and storage for 400 lights, together with a separate engine and dynamo for lighting the mill in the day-time.

MESSRS WOODHOUSE AND RAWSON UNITED (LIMITED).—Mr. F. D. Leslie, who is carrying on the above business on behalf of the debenture holders, reports a satisfactory increase in the amount of business done, and anticipates a full development as time goes on.

MESSRS. W. H. ALLEN AND CO.—The *employés* of the Belfast branch of Messrs. Allen and Co. held their annual outing last week. Warren Point was reached by train, and the party afterwards coached along the sea shore to Newcastle, where an excellent repast was enjoyed. Mr. Kempster, who responded to the toast wishing success to the firm, stated that over thirty steamers in Belfast had received complete equipments of electric lighting plants from that firm's works, in every case the utmost satisfaction being given to their clients. Mr. James McLelland, the Company's Belfast representative, and Mr. Wray, the superintending electrician, congratulated those present on the very cordial relations existing between the *employés* and the firm.

BANDON.—The Town Commissioners, at their meeting last week, resolved to carry out the recommendations of the ratepayers to reject the electric lighting scheme of the Bandon Electric Lighting Company.

BARROW.—At the last meeting of the Town Council it was resolved "that, in order to ascertain whether there is any demand for the electric light, a circular be sent to the householders in the centre of the town asking them to state whether they would be prepared to take a supply, and if so, to what extent."——Mr. R. Hammond gave a lecture upon the cost and utility of electricity in shops and houses on Thursday last week before the Barrow Naturalists' Field Club.

BOLTON.—The Gas Committee of the Corporation met on Friday to consider the revised tenders for the erection of the generating station and other buildings in connection with the scheme for lighting the town by electricity. They recommended the Town Council to accept separate tenders from local firms for the masonry, brickwork, joinery, slating, plumbing, &c., plastering, painting, and excavation work. The Corporation held a special meeting on Wednesday, and adopted the Gas Committee's recommendation.

DERBY.—The Town Council, at their last meeting, voted the Art Gallery Committee £109. 5s. 4d., to defray the cost of fitting up the Art Gallery with the electric light.

DUNDEE.—The Electric Lighting Committee have decided to instal the electric light in several of the streets of the city. 123 gas lamps are to be dispensed with, and in their stead will be erected 36 electric light pillars and lanterns.

EDINBURGH.—The large warerooms of Messrs. Adams and Son, Edinburgh, have recently been lighted by electricity by Mr. M. Buchan. A Crossley gas engine is used with a Royce alternating dynamo, in anticipation of accumulators being subsequently put in.

HASTINGS.—The Secretary of the Hastings Electric Light Company, having intimated that they were unable to obtain the necessary transformers for the extension of the electric light along the front by October 1st, the time fixed by the contract for the commencement of the lighting, the Town Council have agreed to the postponement until March 25th next of the beginning of the additional lighting.

HARROGATE.—A sub-committee reported to the Town Council on Friday that they had conferred with Mr. Wilkinson with reference to his appointment as electrical engineer to the Corporation, and had agreed with him as to the terms upon which he should prepare and carry out the installation in accordance with his report previously made. The sub-committee's report was approved.

HAWICK.—The Town Council had before them last week the question of lighting the town by electricity; but it was decided to defer taking any action in the matter until the ratepayers had had an opportunity of considering the question at the forthcoming ward meetings.

HUYTON-WITH-ROBY.—A letter was read at the last meeting of the Local Board from the British Insulated Wire Company, asking the Board's assistance in their obtaining a Provisional Order, to enable them to supply electric light within the Board's district.

LINCOLN.—The London and Provincial Brush Electric Lighting Company (Limited) having notified the City Council of their intention to apply to the Board of Trade for a Provisional Order to authorise them to supply electricity within the city, the Council have decided to oppose their application, as they themselves possess special facilities for lighting the city by electricity, and are quite prepared to undertake the work as soon as they are satisfied that it would be to the interest and advantage of the inhabitants to supply such a mode of lighting.

MERTHYR.—At the last meeting of the Local Board the Clerk said he had received a reply from the Pontypool Electric Light and Power Company in regard to the proposed electric lighting of Merthyr. The central station at Pontypool was not a large one, there being plant for the supply of 5,000 lights. The Company notified that they would be pleased to show any member of the Board over the station. The letter was referred to the Electric Lighting Committee for consideration.

MONTROSE.—At the meeting of the Town Council on Monday a long report was read from Mr. Wm. A. Bryson, of Glasgow, in reference to the suggestion that the electric light should be introduced into the town. In the course of his report, Mr. Bryson stated that he was strongly of opinion that it would neither be satisfactory nor economical to adopt water as the motor power. He, therefore, suggested the laying down of a small central lighting station with steam engines and boilers, or preferably gas engines and producers, the total cost of which he estimated would be £6,000, or if a large battery of accumulators was added the cost would be increased to £8,000. Details were also given as to the annual cost of maintenance, and Mr. Bryson works out a credit balance to the town of £352, and the price he estimates at 6d. per unit, equivalent to gas at 5s. per 1,000ft. It was agreed to let the report lie over until a future meeting.

NEWCASTLE.—On November 6th an Industrial, Electrical, Manufactures, and General Trades Exhibition is to be opened in St. George's Drill Hall, and will remain open until December 2nd.

NORWICH.—The electric light has just been installed in the United Free Methodist Church in Chapelfield-road, which is the first place of worship in the city that has availed itself of the new illuminant. The chapel itself is fitted with 46 16-c.p. lamps and 18 32-c.p. lamps. There are 4 16-c.p. lamps in connection with the organ, and 12 in the various class-rooms at the rear of the chapel; whilst in the porch there is a very elegant electrolier. The installation has been carried out throughout by Messrs. Laurence, Scott and Co.

SHEFFIELD.—At the last meeting of the Board of Guardians a letter was read from Mr. T. Scott Anderson, asking if the Guardians were disposed to consider the question of the electric lighting of the workhouse, but a resolution was passed that the Guardians could not consider the question at present.

SWINTON AND PENDLEBURY.—At the last meeting of the Local Board, the question of the advisability of the Board seeking a Provisional Order to light the district with the electric light was referred to a committee of the whole Board.

The Glasgow Municipal Telephone Scheme.—At last week's meeting of the Glasgow Town Council Mr. J. H. Martin raised the question of the telephones by saying that it seemed absurd to him to go on with the appointment of a telephone engineer when the committee had as yet only applied for a licence. Several members held that the committee had outrun their remit. Dr. Colquhoun said that if there was one thing clearer than another the step taken at the last meeting in authorising the committee to apply for a licence was a distinct indication that the telephone system in Glasgow was a matter which might very well be municipalised. Mr. Starke closed the discussion by saying that at the last debate he was asked, Where are your reports from experts? He had got reports at his own expense hitherto, and he could assure the Council that not a penny of expense would be incurred for an engineer, or an engineer employed before the licence was obtained, and that no engineer would be employed until the Committee came before the Council. At last the minutes were carried, subject to the understanding that no engineer would be employed until the licence had been obtained and the whole matter had again come before the Council.

NEW COMPANIES, STATUTORY RETURNS, &c.

[*In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1893, pages 320-348, *&c., &c.*]

HARRISON, AINSLIE AND CO. (LIMITED).—This Company has been registered with a capital of £100,000, in £10 shares, to incorporate as a limited company the business of ironfounders, iron merchants, ironmasters, smelters, and steel converters, hitherto carried on by Messrs. Harrison, Ainslie and Co.

ANDERSON, ANDERSON AND ANDERSON (LIMITED).—This Company has been registered, with a capital of £50,000, divided into 1,000 Six per Cent. Cumulative Preference and 4,000 Ordinary shares of £10 each respectively, to acquire the goodwill of the business carried on in London, Bow, Bristol, and Cardiff, under the style of Anderson, Anderson and Anderson.

CHEMICAL AND ELECTROLYTIC SYNDICATE (LIMITED).—This Company has been registered with a capital of £30,000, in £5 shares, to acquire certain patents from Messrs. Lyte and Prof. G. Lunge (of Zürich) connected with the manufacture of bleaching powder, caustic soda, white lead, &c., and to carry on the business of manufacturing chemists, electro-chemists, druggists, bleachers, &c. The first Directors are N. H. Fenner, W. E. B. Blenkinsop, W. MacNab, and H. R. Baynes.

PRINTING TELEGRAPH AND CONSTRUCTION COMPANY OF THE AGENCE HAVAS (LIMITED).—The first return of this Company made up to June 28, 1893, has been filed, when the whole nominal capital of £115,000, in shares of £5 each, was subscribed for; 10,823 of these shares were issued as fully paid, while a call of £2 per share has been made on the remaining 12,177 shares. The calls paid amount to £5 400. 10s., leaving no less than £18,953. 10s. in arrears.

PROVINCIAL ELECTRIC LIGHT AND POWER SUPPLY (LIMITED) and PUTNEY AND HAMMERSMITH ELECTRIC LIGHT AND POWER SUPPLY (LIMITED).—In reply to official inquiries respecting the status of these Companies, V. B. D. Cooper states that no business has been done, and the undertakings have been abandoned upwards of six months.

CITY NOTES, &c.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended September 10th were £751, as against £768 for the corresponding period of last year, being an decrease of £17. The total receipts for the half-year amount to £8,124, against £7,695 in the corresponding period of 1892, being an increase of £429.

CRYSTAL PALACE DISTRICT GAS COMPANY.—At the ordinary general meeting of the shareholders on Friday, the Chairman said that while the extraordinarily fine and hot weather had caused a decrease of 4·47 per cent. in the quantity of gas sold, the competition of the electric light and oil had made no difference to the Company.

Digitized by Google

COMMERCIAL CABLE COMPANY.—A quarterly dividend of 1¾ per cent. has been declared, payable on the 2nd proximo.

WESTERN UNION TELEGRAPH COMPANY.—This Company has declared a quarterly dividend of 1¼ per cent.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended September 8, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £1,919.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 801.—Vol. XXXI. FRIDAY, SEPTEMBER 22, 1893. PRICE FOURPENCE.
Annual Subscription (U.K.), 19/6

NOTES.

The proceedings in Sections A and G cannot be said to have materially contributed this year to the advancement of science, which is the confessed object of the British Association. While other Sections thrive and interest their members with accounts of actual discoveries and with important discussions, Section A is but the *rendezvous* of certain professors, who take this opportunity of interchanging a few ideas before the end of their vacations. Outsiders are permitted to listen to their confabulations, and to take a minor part in the proceedings. As the professors are fortunately among the first rank, most of their ideas are of interest to those who are concerned with physical and mathematical science. On rare occasions some recent research is communicated, and occasionally an important report; but, for the most part, we have to be contented with scraps of theory, a stray problem or two, *réchauffée* of old Papers, and descriptions of instruments employed on important researches, which are themselves communicated to other societies. But the advancement of science, if any, is quite accidental. The teaching of physics in schools seemed to have stirred up a good discussion. The reason is obvious: a very large proportion of the active members of the Section are engaged in educational work.

Of the electrical work done in Section G the less said the better. In an article on this subject in our contemporary, the *Engineer*, a fortnight ago, a quotation was made from *Nature*, and of this we repeat the first sentence. "Unless Section G sets its house in order the mechanical science of the British Association will become a by-word among engineers." A volume might be written on the subject indicated by the title of Mr. G. Kapp's Paper, but he concerned himself chiefly with multiphase intricacies. This might have attracted some attention eighteen months or two years ago, but most of us are tired of talking about multiphase problems. Mr. Snell's Paper, if not another attempt to whip a dead horse, was an endeavour to stimulate a torpid hack. Mr. W. B. Sayers has naturally experimented further with his armature winding, and sent in a few curves to illustrate them. Three indirectly electrical items come under our notice, two Papers by Mr. W. W. Beaumont, one confessedly an improvement on a last year's invention, and the report on graphical methods.

Many an ether has been born in Section A. It would be perhaps convenient to name them after their birthplaces. Thus we have the gyrostatic or Montreal ether, the turbulent-vortex or Manchester ether, and the double-concentric-insulated-spherical-won't-be-worried-by-a-circular-saw ether which may be more conveniently called the Nottingham ether. The British Association has really done something in affording opportunities for the flowering of these hardy annuals, which rarely put out blossoms worthy of adorning the proceedings of a serious scientific society.

During the discussion last Tuesday of a "Supplementary Note on the Ether," read by Prof. Lodge, an interesting point was raised as to the exact basis of distinction between the terms *electrical* and *mechanical* as applied to the interactions between ether and matter. Prof. Lodge seems to take the position that there is no mechanical action between these two forms of substance, and is thus driven to the conclusion that wherever any action between them is known or suspected to occur it must be referred to some electrical action for its explanation. In view of the apparent reluctance which Prof. Lodge showed, to give an exact definition of an electrical action, it must be rather difficult to follow him to any definite conclusion. The fact pointed out by the President of the section, that all optical phenomena are capable of mechanical explanation, must leave the matter still within the region of legitimate doubt.

At the meeting of the British Association at Edinburgh last year, Prof. Hele Shaw presented an elaborate report on the use of graphical methods in mechanical science. We alluded to it at the time, and recorded the brief discussion which took place. The report occupied no less than 159 pages, and though 98 of these were occupied by a bibliography, we found it impossible to give any abstract of it in these columns. Another report has been presented, and we print this week an abstract which has been prepared by the secretary. The report of last year gave a summary rather than a description of graphical methods, and it is hardly correct to say that the interpolation of plotted results was treated fully in it, as is suggested in the present report. Graphical methods have been excluded from educational mathematics, chiefly by reason of the vicious circle of teacher, scholarship, examination, scholar, teacher. It does not seem to attract attention from the band of reformers who meet under the name of the Association for the Improvement of Geometrical Teaching,

Digitized by Google

and we must look to technical colleges and professors of engineering as, for example, Prof. Hele Shaw and Prof. Robert Smith, for the encouragement of this important subject. Meanwhile, as the present report states, on the continent of Europe not only have special courses of lectures been devoted to the teaching of graphic statics, but in both Europe and America the graphic solution of problems has received attention in nearly every engineering course of instruction.

A Paper which excited considerable interest at the first meeting of Section G was the one read by Mr. W. Worby Beaumont on "The Automatic Balance of Reciprocating Mechanism." Although dealing with a purely mechanical subject, and proposing a purely mechanical remedy for one of the ills to which a certain class of machinery is heir, yet there is much interest to electrical engineers in this Paper, from the fact that it proposes a remedy for vibrations such as so commonly occur in high-speed central-station engines, and which have led to such legal difficulties in the past. Proceeding on the optimistic principle that every evil is but good in disguise, Mr. Beaumont does not attempt to stop the vibration by balancing or by stiffening, but proposes to absorb it and make it contribute to the useful effect of the engine. The abstract of his Paper, which will be found in another column, does not explain how this bold system is to be applied in practice.

To have kept up the price of glow lamps at 3s. 9d. until their retail establishments closed on the evening of November 9th would have been a foolish proceeding on the part of the Edison and Swan United Company. Foreign lamps, and cheap ones, are sure to be offered, together with the perhaps half-hatched productions of inexperienced English makers. With the view of retaining as many of their old customers as possible, as well as to show what they can do at a more moderate price, lamps of 8, 10 and 25 candle-power were reduced yesterday to 1s. 9d. It is to be hoped that twelve months hence our central-station managers will not be repeating the lamentations recently indulged in by Herr Clarence Feldmann, electrical engineer to the Cologne municipality, in an address on "Artificial Sources of Light," delivered before the Rhineland and Westphalia Gas, Electricity, and Water Association. "The recent fall in the price of incandescent lamps," says Herr Feldmann, "does not appear to be by any means an unmixed blessing. When we consider what accuracy is required, what perfection in the filament, and how the light produced varies with the potential of the current, being approximately proportional to its sixth power, we see that it will now be more unsafe to rely upon the lamps being correctly adjusted to absorb the right quantity of current at the right potential. The limit of error has hitherto been about 2 per cent. either way, but with the new price, 1s. per lamp, it will hardly be possible to come nearer than 4 volts either way."

The surrender of the Postmaster-General to those importunate Members of Parliament who have demanded that the agreement of the Post Office with the National Telephone Company should be presented to the House of Commons before ratification, has been followed by the announcement that this document will not be laid on the table till November. The penultimate month of the year is, indeed, appropriate to the consideration of a question over which the Post Office and Parliament have succeeded in getting thoroughly befogged. The decision of the Postmaster-General to lay the agreement before the House of Commons in draft form, notwithstanding that a contrary decision was supported by a previous resolution of the House, points to the conclusion that he is excusably anxious to pass some of the odium of a bad bargain on to the gentlemen who are largely responsible for such a bargain being necessary. Up to the present all that we have been able to detect, beyond sound, in the utterances of the legislators who have been prominent in badgering the Postmaster-General, has been something suspiciously like a childlike desire to eat the cake and have it.

The financial position of the Postal Telegraph Service receives greater attention than usual in the Postmaster-General's Report for 1892-3, just issued. Not only is the general business stationary, but in some branches of it there are continued signs of serious decline. Notably is this the case in respect of foreign telegrams, which seem to have suffered a formidable check since the establishment of telephonic communication with the Continent, the receipts from which do not cover the loss. Probably more is due to a similar cause than appears in the report, as touching inland telegrams, which have steadily diminished as telephonic facilities have increased.

Some attempts have been made to stop the inordinate growth of free railway messages, the number of which has for years past been a sore affliction to the Telegraph service. The extravagant length of these franked messages is nothing less than scandalous; and the Postmaster-General would strengthen his demands considerably, we suspect, if he were to make public the nominal value of these free messages, with illustrative examples of how the railway people's average message increases in length while other people's decreases.

After a year of office Mr. A. Morley has discovered that the vote he gave in 1891 for a Parliamentary Committee to inquire into the grievances of telegraphists was founded on a misapprehension, and that any actual grievances remaining can be dealt with by himself alone. Probably if Earl Compton, who now champions the telegraphists' cause, were to succeed Mr. Morley he would make the same discovery—the discovery, namely, that it is easier to give voice to dissatisfaction than to give reasons for it. Earl Compton failed in this; but on the other hand, Mr. Morley fails also in trying to make light of it. That the aggregate amount paid for wages goes on increasing is no proof that the individual wages are sufficient, and that many hundreds of applicants are ready for any superior vacancy does not prove that its emoluments are adequate. Moreover, midst all this agitation amongst the subordinates, it must not be forgotten that in the opinion of many of the higher officials, the superior appointments in the Post Office are the worst paid of any in the public service.

Some two months ago we gave a brief account of an electro-medical contrivance which had just been described before the Académie des Sciences by M. D'Arsonval, but neither the inventor's high standing in the ranks of electro-medical investigators, nor the decidedly original illustration accompanying his memoir, could induce us to employ that fatal monosyllable "new." Our caution has not, however, served us in good stead. The very next week it was our painful duty to have to confess that the instrument used by M. D'Arsonval to measure the high-frequency magnetic fields employed by him had been previously used by someone else for a somewhat similar purpose; and we are now assured by no less than three affidavits, respectively sworn to by "the best known constructor of scientific apparatus in England," by "a member of one of the most respectable printing firms in London, and by a retired member of Her Majesty's Indian Civil Service," that "the inventor and publisher of the supposed new mode of electric treatment recently described by M. D'Arsonval to the Académie des Sciences, which has created such an immense sensation, and suddenly made his name widely known throughout the world, is *not* M. D'Arsonval, but Prof. E. S. D'Odiardi." Be this as it may, Prof. D'Odiardi stated in his original account that "le courant continu ou à des interruptions rares est employé," whilst the whole object of M. D'Arsonval's device was to submit the unfortunate individual inside his cage to the action of *high-frequency* discharges.

Cable Interruption:

	Date of Interruption.
Pernambuco-Ceara	September 1st.

A New French Electrical Journal.—The ranks of the French technical press have received an addition in the shape of an electrical contractor's paper called the *Journal de l'Electricité.*

Pavia.—Signor Luigi Losio has applied for a concession to utilise the water-power of the Naviglio to the extent of 500 H.P. for industrial purposes and for the electric lighting of Pavia.

The Madras Tramways.—By an order dated August 15th, the Madras Government has granted to the Madras Electric Tramways Company the extension of six months asked for from April 6th.

Salford.—Mr. S. J. Smith, Local Government Board Inspector, held an inquiry on Tuesday last, relating to an application by the Salford Corporation for authority to borrow £50,000 for the purpose of electric lighting.

House of Commons Telegraph Business.—Some idea of the business transacted at the House of Commons Post Office may be gathered from the fact that, since the beginning of the present Session no fewer than 102,248 telegrams have been dealt with, as compared with 68,895 in 1891.

British Association Grants.—At the meeting of the General Committee of the British Association on Wednesday a grant of £25 was made to Prof. Carey Foster in connection with electrical standards, and one of £5 to Prof. Oliver Lodge in connection with his movement on behalf of a National Physical Laboratory.

Wakefield.—At a meeting of the Town Council on Thursday last week, the Chairman of the Sanitary Committee proposed a resolution directing that an application should be made on behalf of the Corporation to the Board of Trade for a Provisional Order to authorise the Corporation to supply the electric light. There was practically no opposition, all the members voting for the motion with one exception. Mr. Robert Hammond has been retained to advise the Corporation in the matter.

The Electrical and General Engineering College.—We have received the prospectus of this establishment, which offers instruction in ordinary engineering, general science, and workshop courses. Students are prepared for entering the City and Guilds of London Institute, Cooper's Hill, and other colleges. Further particulars may be obtained from the Principal, Mr. G. W. de Tunzelmann, Penywern House, 2 and 4, Penywern-road, London, S.W.

Proposed International Electrical Exhibition in Geneva in 1896.—Even Chicago does not appear to have damped some people's ardour in the matter of exhibitions, and it is just possible that the opening of the magnificent and unique water-works at Geneva in 1896 may be an inducement to many to submit to yet another of these inflictions. The promoters of the Geneva Exhibition hope to be able on the neutral ground of Geneva to hold a really international show, and not a more or less local repetition of the Frankfort Exhibition.

Electricity in Mines.—The Baker's Creek Gold Mine, in New South Wales, is amongst the latest mines which it is proposed to work and light by electricity, an agreement having been entered into with the Hillgrove and Armidale Water-Power Electric Company, by which the works are to be supplied with 100 H.P. from the proposed electric works to be constructed at the Gyra Falls, about four miles from the property. It is estimated that a saving of little short of £1,000 a year will by this means be effected in working the machinery and lighting the mines, and it is expected that the change will be made not later than March, 1894.

The Electrolytic Treatment of Sewage.—A system of disinfecting town sewage, somewhat similar to that in use at Brewsters (N.Y.), is now being tested by Messrs. Merryweather and Sons, specially with a view to dealing with the drainage of seaside towns. The idea is that of electrically treating sea water, and thereby effecting such chemical changes as to render it a powerful disinfecting solution. A portable "Squires" engine is being used, with a dynamo bolted to its carriage for supplying the electric current, and the new disinfectant is pumped into the sewers by the same engine, the firm's hydraulic sewer flushing apparatus being employed.

Paris Universal Exhibition, 1900.—A decree organising the proposed Paris Universal Exhibition of 1900 has been published in the French *Journal Officiel.* Accompanying the decree is a report by the Minister of Commerce, M. Terrier, explaining that the unprecedented scale on which the project is to be carried out, the difficulties which may arise in regard to the retention of some of the buildings on the Champ de Mars, and the means to be adopted for the conveyance of visitors, necessitate this early notification. M. Alfred Picard, who filled the office of *Rapporteur Général* for the 1889 Exhibition is appointed Commissary-General. He will be assisted by a Consultative Committee of 100 members.

Brazilian Telegraphic Business.—The Managing Director of the Western and Brazilian Telegraph Company, under date of September 15th, writes us as follows:—

> Sir,—With reference to a telegram purporting to have emanated from Buenos Ayres and addressed to the President of the Central and South American Telegraph Company, stating that the office of this Company at Rio Janeiro had been abandoned by the staff, permit me to inform you that this Company has two offices at Rio Janeiro, the one in the city which has been closed, being in the line of fire, and as its use was not permitted it was useless to subject the men to unnecessary risk; the other office, a short distance from the town, is out of the scene of operations, and has not been interfered with, thus when hostilities cease and we are permitted to recommence business, telegrams will be subject to no delay of any sort whatever. In the meantime, "through traffic" with the River Plate is not interfered with by our route.

——Under date September 20th, the Eastern and Brazilian Telegraph Companies notify that telegrams written in plain language and of a non-political character can be accepted for Brazil.

The Decimal System in the United States.—At an engineering Congress held at Chicago on August 1st last, which was attended by leading members of the profession from many countries, a Paper on the fundamental units of measure was read by Mr. T. C. Mendenhall, who is superintendent of the United States Coast and Geodetic Survey, as well as Superintendent of the Standard Weights and Measures at Washington.

Digitized by Google

Mr. Mendenhall stated, *inter alia*, that the office of weights and measures at Washington, with the approval of the secretary of the Treasury, would in the future regard the international prototype metre and kilogramme as fundamental standards; and the customary units, the yard and the pound, would as from April 5, 1893, be treated as derived therefrom. This amounts to an official notification that the United States have formally adopted the metre as the standard of measurement. In future the yard will be represented as a fraction of the metre and the pound as a fraction of the kilogramme in the Washington office of weights and measures.

The Cost of the Chicago Exhibition.—According to the *Engineer* the Chicago Exhibition has cost $23,867,752 to August 7th for construction and administration. The gate receipts to the same date were $3,447,037, and receipts from concessions $1,178,546. The daily receipts from all sources are about $80,000, and the average daily expenses $15,000, leaving a net daily revenue of $65,000. Auditor Ackerman, in his condensed balance-sheet of July 31st, charges to construction account a total of $18,819,198; to general and operating expenses $4,957,879, and to preliminary organisation $90,674. Assuming that the Exhibition will remain open for 60 days from August 7th, this leaves a profit of about $4,000,000. Adding $4,600,000 previously received, we have a total net profit of $8,600,000, deducting this from the cost, we see that a balance of about $16,000,000, or nearly £3,000,000, remains to be met. The Chicago Exhibition represents the largest money loss that has ever been incurred by an Exhibition. The greater number of the Chicago hotels have gone into liquidation or been closed. The insurance companies have withdrawn their policies on several of the caravanseries especially constructed to accommodate a countless crowd of visitors who have never arrived. The insurance companies assert that in the interests of morality it is wrong to tempt the hotel keepers to commit arson, the average of visitors to these hotels being from 7 to 10 per cent. only of that expected and provided for. The visitors are, indeed, mostly country folk, coming from a radius of about 300 to 500 miles. Probably no other scheme introduced to the world with such a blowing of trumpets has, says our contemporary, ever fallen so flat.

Proposed British Association Arrangements for 1894 and 1895.—A meeting of the General Committee of the British Association was held at Nottingham on Monday for the purpose of determining upon the place of meeting the year after next. A deputation attended from Toronto and Prof. Mavor explained the facilities which Toronto afforded for the holding of general and sectional meetings. Sir Douglas Galton wished to know whether any additional facilities would be offered, such as those which were enjoyed by British members when the Association met at Montreal. Prof. Mavor was not prepared to say that the Dominion would, as on the former occasion, bear a portion of the cost of the passage-money of British members. It was moved by Sir Douglas Galton that the committee desired to express their best thanks to the Provisional Committee of Toronto for the invitation, and provided that suitable arrangements could be made similar to those that were made for the Montreal visit the committee would be prepared to entertain the question of meeting at Toronto before many years had elapsed. The conclusion of the resolution provoked some laughter. It was then put and agreed to. Deputations were then introduced from Bournemouth and Ipswich, the statement of whose rival claims afforded a good deal of amusement. On the question being put to the vote, there appeared 31 for Ipswich and 20 for Bournemouth. It was, therefore, decided that the meeting of 1895 should be held at Ipswich. On the motion of Sir Frederick Bramwell, seconded by Sir W. H. Flower, the Marquis of Salisbury was nominated President of the meeting next year at Oxford.

A Tasmanian Copper Mine.—In an article entitled "A 'Rio Tinto' for Tasmania," *The Statist* of last week dilates on a wonderful copper find in Tasmania. In metalliferous discoveries Australasia has, says our financial contemporary, been a land of surprises. It is a pretty well-known story now how a shepherd discovered the existence of silver, which has proved so abundant in the Broken Hill district in New South Wales. The Mount Bischoff tin deposits in Tasmania were a surprise, as also were the Mount Zeehan silver lead deposits in the same colony. But as regards the last-named colony there is yet another surprise, and one of very considerable interest, not to say importance. It would appear from the reports of unimpeachable experts that there is an immense copper deposit at Mount Lyell, near Zeehan. This deposit has been exploited by a colonially-formed Company. Apparently the deposit exceeds that of the well-known Tharsis Company; and though the Rio Tinto mine so called is a Goliath alongside the new Tasmanian property, so far as the copper deposits have been proved the Mount Lyell copper deposit we have referred to promises to be of very great commercial importance. The first consignment of about ten tons of ore was assayed in the colony as 1,054 ounces of silver to the ton and 20 per cent. of copper. The assay on which the sale was made, of the same quantity, was 1,250 ounces of silver and 26 per cent. of copper. One of the fortunate conditions as regards the position of the property is an immense water power—in one part a fall of 400ft., and in another part a fall of 1,000ft. The one, representing, in a dry season, 300 horse-power and the other over 2,000 horse-power. It is proposed to utilise this, the water-power being used to generate electrical power. Electricity will be applied as power for every mechanical purpose, and possibly also for producing refined copper, and separating at the same time the gold and silver. From what has actually been proved, it is estimated there are some 4½ million tons of ore accessible, to say nothing of what is believed, but has not yet been proved, to exist. One particular point about the new discovery is that apparently the deposits can be worked in a manner similar to the Rio Tinto deposits, that is, by terraces and cutting down the ore as from the side of a hill; in other words, bodily removing a portion of the side of a hill, the part removed consisting entirely of copper ore.

The Accident at the Blackfriars Transformer Sub-Station. An inquest was held at Guy's Hospital on Friday last by Mr. A. C. Langham, Deputy Coroner for Southwark, with reference to the death of Frederick William Ball, aged 35, of Alfred-street, Battersea Park-road, who was killed by an electric shock on the previous Tuesday afternoon. Major Cardew represented the Board of Trade.—Philip Hunt stated that on Tuesday night last week, about half-past six o'clock, he was called into the converter-house of the London Electric Supply Corporation, Blackfriars-road, where he found the deceased lying on the floor between two converters and a stool. He appeared to be dead. A young man named Meech was at the door very badly burned. The witness at once telephoned to one of the other stations for assistance. Witness was not employed by the Corporation, but he worked on the same premises.—John George Freeman, the engineer in charge of the London Electric Supply Corporation station at Blackfriars, stated that on receiving the telephone message for help he at once took a cab, and arrived at the Blackfriars station shortly after seven o'clock. Meech, the assistant linesman, was sitting on a stool, whilst Ball was lying on the ground dead, with outstretched arms, near transformer 42. The deceased had been in the Corporation's employment for a number of years. He was always a very careful man, and must have been aware of the danger he incurred when dusting with the plug in the omnibus bar.—Mr. P. W. d'Alton, engineer-in-chief to the London Electric Supply Corporation, said the deceased had the reputation of being an exceptionally careful, trustworthy man, and that he knew every bolt in the building. It was a piece of lamentable forgetfulness on his part not to have removed the plug before commencing to dust. Meech's duty required no previous knowledge of electricity. Notices, with "Dangerous" on them, were posted over the machinery.—Dr. Hamilton, house surgeon, said he saw the deceased between seven and eight on Tuesday evening. There was a ragged wound on the back of his right wrist and hand, and the flesh was charred and smelt of burning. There was also a smaller wound on the back of the left wrist, and the injuries had the appearance of having been caused through contact with electricity.—Other evidence showed that Meech had been very badly burned, and would not be able to leave the hospital for some time; and the inquiry was eventually adjourned for a month for his attendance.

LANDMARKS IN THE HISTORY OF ELECTRO-CHEMISTRY.*

BY W. W. HALDANE GEE, B.SC., F.C.S.

(*Concluded from page 530.*)

l experimenters were greatly mystified by the evolution drogen and oxygen at a distance from each other during electrolysis of water. Some conceived the curious idea water is a simple substance, which, when positively rified, becomes oxygen, and when negatively electrified mes hydrogen. To others it appeared that the galvanic t was a peculiar acid, as appeared from its taste, its power eddening litmus, of oxidising metals, and of forming . The subject was further complicated by the observa- that the purest water yielded, on electrolysis, both acid alkali.

ery fortunate was it for electrical and chemical science there was at this critical time a philosopher prepared to on experiment rather than on conjecture. Davy had been

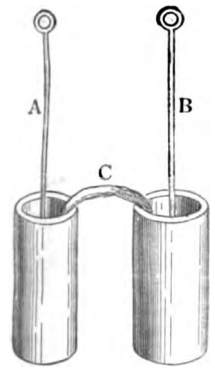

Fig. 6.

verfully impressed by the experiments of Carlisle and cholson. In it he perceived the connection of electricity l chemistry. His first paper on this line of work appeared September, 1800. It was followed in quick succession by others, in one of which he says: "But a short period has psed since philosophers beheld with wonder solid and fluid bstances assuming new modes of existence in different gases. not the new phenomena of galvanism authorise us to hope t at no very distant time they will behold even the gases dergoing novel changes and existing in new and unknown ms?" On his appointment at the Royal Institution, he de galvanism the subject of his first course of lectures, l it was likewise the subject of his first communication to the yal Society. Passing by his earlier work, those researches ich had such an important bearing on chemistry will be cribed.

Davy's first Bakerian lecture was devoted to the description his experiments on the fact above mentioned, that acid and ali are obtained during the electrolysis of water. Believing that glass vessels might yield some of their substance to the water, he first used small cups of agate (Fig. 6).

These were connected at C with very white and transparent asbestos. Pure water was placed in the cups, and the electric current passed. After 48 hours, it was found that one cup contained acid, and the other alkali. Thus the result was similar when agate cups were used to that with ordinary glass vessels. Being still unsatisfied, however, with regard to the question of the possible influence of the nature of the vessel, he repeated the electrolysis many times, using the same agate cups. With each repetition of the experiment it was found that although the amount of acid produced appeared not to have changed, yet the quantity of alkali steadily diminished. From this fact he concluded that the alkali was due to the abstraction of a constituent present in small quantity in the agate, this constituent being almost entirely removed by the end of his frequently repeated experiments. His next modification was the employment of vessels of a material entirely different in its chemical nature from either glass or agate. He constructed cups of gold of the form shown in Fig. 7.

On electrolysis alkali was again found, though in smaller quantity. Reflecting that the water used had been distilled from a *glass* retort, Davy purified the water for his experiment by distillation in a silver still. On electrolysing this water in the gold cups alkali was no longer found. He had then definitely shown that the alkali was due to contamination of the water, and had traced the source of this contamination. The acid, however, still appeared. On testing, he came to the conclusion that the acid produced was nitric acid, which he knew, from the experiments of Cavendish, to be produced from *air* by means of electricity. He devised a special apparatus for the electrolysis of water out of contact with air, collecting the gases formed. In this final experiment he showed that pure water electrolysed out of contact of air in an apparatus made of gold, is decomposed with the formation of the well-known gases, and of no other substance whatsoever.

After the completion of this model of scientific research, Davy turned his attention to the decomposition of solid bodies.

Two cups of compact sulphate of lime, treated by the method previously employed, gave sulphuric acid and lime. Various minerals, as lepidolite and zeolites, were decomposed in the same manner, and some interesting experiments were performed on the transference of substances during electrolysis. In these the glass apparatus shown in Figs. 8 and 9 was employed. Some of these experiments were extensions of those of Berzelius and Heisinger who, about the year 1803, observed the following laws:—(1) Oxygen and acids are accumulated round the positive pole, while hydrogen, alkalies, earths, and metals are accumulated round the negative pole; (2) Acids and bases may be made to pass through a considerable column of water, and even to cross each other in order to accumulate round the poles to which they are respectively attracted.*

Owing to the constant appearance of certain bodies at particular poles, the division of elements into electro-positive and electro-negative was suggested. It appeared as if any compound could be regarded as consisting of two parts, one electro-positive, the other electro-negative. Bodies with chemical affinity for each other were regarded as being in opposite electrical states, the energy of combination being proportional to the difference of electrical tension. Chemical affinity and electrical attraction were considered by Davy to have a common origin. The dualistic theory of Berzelius, a modification of that of Davy, has had an important influence on chemical theory.† The consideration of these early attempts at harmonising chemical and electrical facts are of peculiar interest at the present time, in the light of the recent advances due to the researches of Arrhenius, Ostwald, and others.

Davy was unremitting in his researches in the field of electro-chemistry. A year after the first Bakerian lecture he

The substance of these articles was originally read at a meeting of the ens College Chemical Society. For some help in preparing for publica- I am indebted to Mr. Vaughan Cornish, M.Sc., F.C.S.

* The Paper containing these experiments was first published by Gehlen in his Journal in 1803. It was afterwards published by Berzelius in Swedish in 1806. (*See* Thomson's "System of Chemistry," Vol. I., 1817. p. 175.)

†*See* Wurtz's "History of Chemical Theory," translated by Watts, p. 67

published the discovery of potassium and sodium. In this work he used a combination of batteries, 274 plates in all. Connecting a platinum spoon with one end of the battery he fused in the spoon some caustic potash. On bringing a platinum wire connected with the other end of the battery into the fused potash some brilliant phenomena occurred. When the wire was connected with the negative pole a most intense light was emitted, and a column of flame, which seemed to be due to the development of combustible matter rose, from the point of contact. When the spoon was connected with the negative pole globules which inflamed in the air rose through the potash. Attempts were made to collect these globules, but without success until the happy device was hit upon of making the electric current the common agent for fusion and decomposition. Potash when dry is a non-conductor of electricity, but a slight addition of moisture gives it conducting power. A small piece of pure potash, moist on the surface from exposure to the atmosphere, was placed on a disc of platinum in connection with the negative side of the battery of 250 elements in a state of intense activity, and a platinum wire communicating with the positive side was brought to the upper surface of the alkali. A vivid action soon took place, and small globules of a high metallic lustre, like quicksilver, made their appearance. These were the sought-for "basis of potash." When Davy first saw the minute globules burst through the potash and take fire he could not contain his delight, but careered round the room in ecstacy.* At the Royal Institution may be seen his note-book in which his description of an improved method terminates with the words "a capital experiment."† This "capital experiment" was the commencement of a long and brilliant research. Soda soon yielded its "basis" to the same methods. A lengthy investigation of the properties of potassium and sodium followed. They appeared like the *alkahests* of the alchemists, imagined substances capable of acting upon everything with which they came in contact. The properties of these metals are familiar enough now, but it is not difficult to understand the intense interest which they excited at the time. The Bakerian lecture occupies 44 quarto pages, full of valuable preliminary results. Unfortunately, the work was interrupted by a dangerous illness.

During this illness of Davy the fame of his researches caused great interest and emulation in France, with which country England was then at war. The spirit of rivalry, perhaps, stimulated Napoleon to grant funds for the construction of a monster battery (*see* Fig. 10). "S. M. I. et R. desired that France should possess a pile stronger than any in existence, in order that it might be seen if elementary substances, which have hitherto remained undecomposed by ordinary means, would yield to an agent so powerful. In a short space of time a battery was constructed of 600 pairs of about 9 square decimeters area, together with others of a smaller size." (Gay-Lussac et Thenard: "Recherches Physico-Chimiques.")

Each pair of the great battery was composed of a copper plate of a kilogram weight, and another of zinc of a weight of three kilograms. The physiological effects were unbearable, and even dangerous, the effects of the shock being felt for several days. The battery decomposed potash and soda with great rapidity, the potassium and sodium burning, as they formed, with jets of fire like an artificial volcano. The action, however, soon ceased, and in twenty minutes the battery had run down. The great battery was not destined to be of much service to chemistry. The difficulty of obtaining potassium and sodium in any considerable quantity by electrical means was so great that Gay-Lussac and Thenard determined to try other methods. They finally adopted the process which still bears their names. These workers traversed very nearly the same ground as that gone over by Davy; their object being the same, viz.: the application of electricity to chemistry. If any spur had been needed to stimulate Davy on his return to health, it would have been supplied by the concurrent research of the French workers. In the opening lecture of the first course which he gave after his recovery, he said, "It will be seen that Volta has presented us with a key which promises to lay open some of the most mysterious recesses of nature. Till his discovery our means were limited, the field of pneumatic research had been exhausted, and little remained for the experimentalist except minute and laborious processes. There is now before us a boundless prospect of novelty in science, a country unexplored, but noble and fertile in aspect, a Land of Promise in philosophy." With undiminished enthusiasm he recommenced work. A voltaic battery of 600 double plates had been provided for him during his convalescence, and when it was thought necessary to have a battery of 2,000 plates it was constructed, the expense being met by subscription. The alkaine earths were subjected to the new method of analysis, with some success. Boracic acid was made to yield boron, whilst, on the other hand, the elementary nature of sulphur, phosphorus, and carbon was confirmed by their remaining undecomposed.

During the progress of these electro-chemical researches, Davy observed that charcoal intensely heated by galvanic agency was not acted on by oxymuriatic acid, not a trace of carbon monoxide, or of carbonic acid, being formed. This led him ultimately to proclaim that the substance discovered by Scheele, the nature of which as an oxidation product of muriatic acid had hitherto remained undoubted, was in fact an elementary substance, for which he proposed the name *chlorine*. This opinion, which traversed the position taken up by the French School of Chemists, was keenly debated, but the accumulation of experimental evidence showed conclusively that Davy's view was correct. As a consequence, the prevailing theory of the constitution of salts had to be modified.

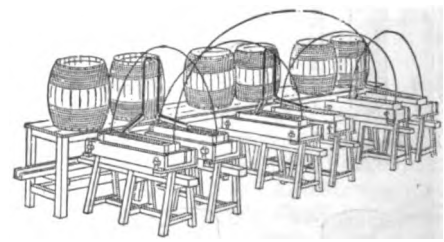

Fig. 10.—The battery of Gay-Lussac and Thenard.

The mantle of Davy as an electro-chemist descended upon Faraday, his successor at the Royal Institution. The isolated facts which the industry of experimentalists had collected between the years 1800 and 1830 he arranged in a philosophical system. He showed that electro-chemical deposition does not depend upon a direct attraction by the poles. The character of the bounding surfaces by which the current enters appears to be a matter of indifference when the liberated materials have no chemical action upon the poles. The poles are only the doors by which the current passes into or out of the decomposing body. The term *pole* had hitherto been applied only to metallic surfaces; a new word was therefore desirable, and Faraday proposed *electrode*. The terms anode, cathode, ion, anion, cation, electrolysis, and electrolyte were likewise coined by him. They were invented in order to obtain greater clearness in expressing his views on electro-chemical decomposition. An early result of his *electrolytical* researches was to learn that the liquid state is necessary for electrolysis. An instrument for measuring currents, *i.e.*, the *quantity* of electricity conveyed by a current, being needed, he invented the volta-electrometer, or, as it would now be termed, the voltameter. An exhaustive research showed him that the indications of the instrument were reliable under the most diverse conditions. Thus he proved that the form of the electrodes and the strength of solution were without effect upon its indications. Using these instruments, he was able to prove with respect to water what he calls the very extraordinary and important principle, that, when subjected to the influence of the electric current, a quantity of water is decomposed which is in every case exactly proportional to the quantity of electricity which has passed, notwithstanding every possible variation in the other conditions.

HORSE-POWER AND THE WATT.

While every elementary student, if not every school-boy, knows that the scientific world has been wrestling for years over the last decimal place or two in the value of the ohm, and while many over-conscientious young engineers use 3·1416 for the value of π in their calculations, everybody swallows 746 watts to the horse-power, as if nature had obligingly arranged that a convenient integral number should express the relation. As a matter of fact there is a small error of about one in ten thousand. The horse-power is, of course, 33,000 standard foot-pounds per minute, and the watt is 10^7 ergs per second. The former of these is a gravity measure of power; the latter a C.G.S., or "absolute" measure. It might at first sight be supposed that, this being so, the relation between the two units would have a geographical variation, inasmuch as g varies with latitude. In fact, we have met with otherwise excellent and reliable physical treatises in which this erroneous view is held; books which even give a table of the different numbers of watts in a horse-power at different latitudes. Now, although there is a perceptible difference in the work done in raising 33,000lb. one foot high at two different latitudes, the work in each case will not be the true measure of a horse-power at that place. The gravity unit of work is not the work done in lifting a pound one foot vertically at *any* latitude; but is defined to be the work which would be done by performing this operation at one definite place on the earth's surface, viz., at Greenwich sea-level. This difficulty is carefully avoided in the G.G.S. system by the device of an acceleration unit of work, instead of a gravitation unit. The number of watts in one horse-power is, then, always the same at whatever place on the earth's surface or interior the comparison may be made; but this number is not exactly 746. The force of gravity on one pound, at Greenwich sea-level, is found to be $981{\cdot}17 \times 453{\cdot}59$ dynes. If the pound is raised one foot, or 30·480cms., the work done will be $981{\cdot}17 \times 453{\cdot}59 \times 30{\cdot}480 = 13{,}565{,}100$ ergs. Since one horse-power is 550 foot pounds per second, this is equivalent to $550 \times 13{,}565{,}100$ ergs per second, which is equal to 746 081 watts.

Only a very small and quite negligible error would be introduced by taking 746 watts to 1 H.P. if the watts are strictly scientific. Engineers, however, are not provided with instruments for measuring volts, amperes, and ohms according to their absolute scientific standard. The ampere may be assumed to be an exact tenth of the absolute unit of current; but the volt of commerce, the volt which is commonly used in determining the power supplied by a central station, differs appreciably from 10^8 C.G.S. units. The direct cause of this is, of course, the determination of the standard ohm, and the closer the approximation of this standard to 10^9 C.G.S. units of resistance the more correct will it be to take 746 commercially-measured watts as being equal to 1 H P.

For instance, if the standard of resistance of 1884 be taken, which is specified as the resistance at the temperature of melting ice of a column of pure mercury 106cm. long and 1 sq. mm. cross section, it will be found that the "volt" due to the flow of exactly one ampere through this resistance will be equal to 0·998 of a true volt. Practical men will not, however, be very much troubled on this account, for the error is only 0 2 per cent. On the other hand, the ohm has received a much more exact determination since 1884; it is now generally defined as being equal to the resistance of 106·3cm of the column of mercury specified above. Practical measurements based on units derived from this evaluation will be much nearer to the truth.

The ohm, the volt, and the ampere are bound up together with the horse-power by definition, and the relation between the volt-ampere or watt and the horse-power is thus fixed at 746·081. No error in the determination of the ohm or either of the other units can affect this relation If anybody having carefully measured a horse-power electrically, and found, after making all necessary experimental corrections that it was equivalent to 748·2 watts, the explanation would be that his electrical standards were wrong, and that he had been using a Paris ohm of 160cm. instead of 106·3cm.

DR. OETTEL'S RESEARCHES ON THE ELECTRO-DEPOSITION OF COPPER.

Dr. Felix Oettel, whose contributions to the study of the conditions affecting the electro-deposition of copper in the voltameter have been noticed in these columns (see *The Electrician*, May 19th, p. 59), has recently published a further account of his investigations in the pages of the *Chemiker Zeitung*. He states that he has observed that a plate of copper suspended, without separate electrical connection, between similar plates acting as the electrodes of a depositing cell, receives on the side facing the anode a deposit of copper, and loses from that opposite the cathode a corresponding amount of metal, and hastens to claim priority in the recognition of this phenomenon, which he considers completely analogous to an inductive effect. Having thus protected his privileges as the earliest in the field of scientific research, he proceeds to act as a pioneer of technical application by suggesting the utilisation of the method in question for refining copper on a manufacturing scale.

Nothing could well exceed the accuracy of Dr. Oettel's observations or the logic of his deductions. That both are inexpugnable is amply evident from the fact that the method of arranging electrodes in a refining vat, advocated by him, has been in extensive use for several years, notably in America, where two or three well-known patented systems are particularly in favour. The description of the best of these systems, and the discussion of their respective merits, appeared in *The Electrician*, Vol. XXIX., p. 222, in an article dealing with the progress of the electrolytic refining of copper in the States. It serves as a piquant commentary on the supposed perfection of international communication and interchange of ideas and information, to find a German chemist occupying a considerable amount of space in a leading chemical newspaper with a communication, obviously written in perfect good faith, dealing with facts of quite respectable antiquity, as if they were noteworthy novelties.

Fortunately, the circumstance that Dr. Oettel is unacquainted with fairly recent progress in matters electrolytic, has led him to take an interest in the phenomena which he has examined, not usually forthcoming on behalf of the trite. Thus he has studied the relation of the quantity of copper transferred to and from the middle plate with that dissolved from the anode and deposited upon the cathode. Working with plates 86 × 131mm., not completely filling the cross section of the depositing cell, he found that the amount dissolved from the one side of the middle plate was about as much greater than that deposited on its other side as was the quantity dissolved from the anode greater than that deposited on the cathode, the difference in each case being due to the use of commercial copper, containing 98·8 per cent. Cu, for all three plates. The quantity of copper deposited on the middle plate was 87 per cent. of that appearing at the cathode, but this proportion would obviously vary according to the arrangement of the plates in the cell. A second experiment with a series of six plates, of which only those at the ends were connected directly with the battery, the plates being 90 × 95mm., and the current density 1·3 ampere per sq. decimetre, gave a deposit of copper on one side of each of the intermediate plates, ranging from 63 4 to 66 9 per cent. of the quantity thrown down on the cathode. The chief conditions influencing this ratio are:—(1) the size of the intermediate plates relative to the cross-section of the cell, or, in other words, the proportion borne by the metallic to the electrolytic conductor in a cross-section including a middle plate, and (2) the absolute size of the plates, the well-known tendency for copper to deposit more densely at the edges of the plates having obviously an effect on the total quantity of copper deposited, which augments as the length of the edges increases relative to the area of the plate, *i.e.*, as the size of the plate diminishes.

Further experiments showed that, given an identity of material for the plates and of distance between them, the drop of voltage was sensibly constant for the series, but that when an unattacked plate, *e.g.*, one of lead, was inserted in the series the drop of voltage from its anode side to the cathode side of its neighbour was necessarily increased, by reason of the fact that

Digitized by Google

the work done was no longer the mere overcoming of the resistance of the electrolyte, but also involved the liberation of oxygen at the anode surface, results which might reasonably have been anticipated. Convinced of the necessity for a characteristic title for the arrangement of electrodes, with which Dr. Oettel has sought to identify himself, he proposes the term "kammerschaltung," *anglicé* "chamber arrangement," to distinguish it from the more ordinary methods of disposing the plates in series or parallel, to which his knowledge has been hitherto confined. We commend the innovation to the attention of electricians and chemists engaged in the electrolytic refining of copper.

REPORT OF THE ELECTRICAL STANDARDS COMMITTEE OF THE BRITISH ASSOCIATION.

The work of testing resistance coils at the Cavendish Laboratory has been continued. A table of the coils tested is given. They have all been "ohms," as defined by the resolution of the Committee given in their last report, and since adopted by the Board of Trade Committee on electrical standards in the following form :—

The resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice 14·4521 grammes in mass, of a constant cross-sectional area, and of a length of 106·3cm., may be taken as 1 ohm. The relation between the B.A. unit and the ohm is the following :—

1 B.A. unit = 0·9866 ohm.

The resolutions adopted by the Committee at Edinburgh were communicated to the Electrical Standards Committee of the Board of Trade. After consideration, the Board of Trade Committee drew up an amended report, in harmony with the Edinburgh resolutions, for presentation to the President (*see* Appendix I.).

The resolutions were accepted at Edinburgh by Dr. von Helmholtz on behalf of Germany, while in France an official committee decided last June to adhere to the propositions of the Board of Trade. Austria and Italy are connected by treaty with Germany for telegraph purposes, and in consequence adopt the same units.

The Committee have learned with pleasure from Mr. W. H. Preece, one of the English delegates to the International Congress of Electricians at Chicago, that the Congress has accepted a series of resolutions defining the fundamental units practically identical with the Edinburgh resolutions.

Thus these resolutions have now been accepted as a basis for legislation throughout the British Empire, the whole of western Europe, and the United States of America.

The Committee are also informed that the Chicago Congress have adopted the name Henry for the unit of self induction. While looking with favour on his suggestion, they think it desirable to postpone definite action until the official report of the Congress has been received.

In March last M. Mascart wrote to the Secretary asking the opinion of the Committee as to a name for the standard of resistance defined at Edinburgh. A circular letter was issued inviting members of the Committee to express their views on four names which had been suggested, viz., "International," "Normal," "Etalon," or "Ohm de 1893." After receiving replies to the circular from 12 members of the Committee, the Secretary wrote to Prof. Mascart to the effect that the number of members who expressed a preference for the name "International" was greater than the number declaring in favour of any other name, but that he thought that the Committee would accept whichever of the first three suggestions commended itself to the French Committe appointed to deal with the matter.

During the year Dr. Muirhead has re-measured his standard condenser. He now finds as the capacity of a condenser constructed 23 years ago to represent 0·1 microfarad (B.A.U.) the value 0·09998 microfarad.

Tests have been made during the year on the 1 ohm and 10-ohm standards of the Association. These are still being continued. The 100 ohm and 1,000-ohm standards have now been delivered, and the tests will be shortly proceeded with. Some experiments were made as to the amount of heating in the coils produced by the current used for testing. These are detailed in an Appendix. Further valuable information on this point is contained in Mr. Griffiths' Paper on "The Value of the Mechanical Equivalent of Heat."

The Committee think it desirable that they should be in a position to complete the set of resistance standards of the Association, and recommend, therefore, that they be reappointed, with a grant of £25, that Prof. G. Carey Foster be chairman, and Mr. R. T. Glazebrook secretary.

THE DEVELOPMENT OF GRAPHIC METHODS IN MECHANICAL SCIENCE.*

Graphical Solution of Problems.

In the absence of Mr. Preece (Chairman of this Committee) and of Lord Kelvin and Sir Benjamin Baker, it devolves upon me, as secretary of the Committee on Graphical Methods, to present a brief extract of the report. The first and preliminary report on this subject was presented in 1889. The second report was presented last year, and was divided into four parts :—

(1.) General geometrical considerations.
(2.) The representation of results graphically.
(3.) Graphical solution of problems.
(4.) A tabulated list of reference to graphic methods to be found in the scientific literature of this country.

Only a brief treatment of the third division was possible. This included quotations from various authors concerning the development of the subject, and a summary of graphical problems, though a more complete account was given of these branches, viz., slide rules and mechanical integrators. The present Committee was appointed to prepare a third report on the subject, dealing as completely as possible with the unfinished portion of the second report, viz., "The Solution of Problems." The study of the second report, particularly of the classified list of references, conclusively shows that graphical solutions have, in this country at any rate, almost entirely proceeded on two lines.

(1.) Interpolation of plotted results.
(2.) Use of reciprocal diagrams in structures.

The former, although arriving at results which would be difficult, if not impossible, to obtain in any other way, is itself a remarkably simple operation, the chief part of the work really consisting in the preparation of the diagrams in which the interpolation is made. This matter was treated very fully in the second report, both for plotted curves and instrumental methods for obtaining them. The latter, namely, the use of reciprocal diagrams, was largely employed, chiefly because of their simplicity. It forms, however, only one branch of what is now known as graphical statics, which in turn only include one class, although the most important class of graphical problems. There has been such a large amount of research in connection with the solution of problems that it is impossible in the compass of a report to do more than to give a summary of this problem. What, however, is extremely necessary at the present time is a general treatment of the methods upon which the solution of all problems is founded. It is also important that some definite recommendation should be made concerning the teaching of graphical methods, the practice in which differs extremely in various parts of the world. The following is, therefore, the scheme adopted in the report :—

Division I.—Graphical outlines in general.

Division II.—Summary of problems which have graphical solutions.

Division III.—The teaching of graphical methods.

The Secretary of the Committee then proceeded to give a short account of the Report under the three above headings :—

(1.) Division I. chiefly consists of a discussion of the operations with segments or lines, which are the only means of graphical calculation, definite portions of lines representing numerical quantities, and only such geometrical operations (being of interest) as enable definite numerical results to be obtained. The first subject discussed is the operations with segments which have been classified in books under the title of "Operation with Lines," or as "Graphic Arithmetic," and various suggestions are made as to the views

* Third report of the British Association Committee, consisting of Mr. W. H. Preece, Lord Kelvin, Sir Benjamin Baker, and Prof. H. S. Hele-Shaw (secretary).

Digitized by Google

which should be held on what may be called simple graphical operations. The following sections are then treated :—(*a*) Representation of areas and volumes by means of segments, (*b*) the additions of segments, (*c*) the combinations of segments, (*d*) the multiplication of segments, (*e*) the summation of the funicular polygon, (*f*) centroids and moments of inertia (derived diagrams), ( ) central ellipse and kern, (*h*) the sum of the products of non-parallel segments, (*i*) properties of reciprocity, (*j*) the null or focal system.

(2.) Division II. has the following heading :—(*a*) Force in its application to bodies considered as being rigid, (*b*) force in its application to bodies considered as being elastic, (*c*) machines, (*d*) hydro-mechanics and naval architecture, (*e*) miscellaneous.

Under the heading (*a*) are classified the general treatment of external and internal forces, framework, arches, retaining walls and tunnels, masonry piers ; (*b*) includes the simple beam, elastic line and curve of deflection, continuous girders, elastic arch.

(3.) Division III. the examination into the treatises and systems of dealing with graphical methods which has been necessary in the preparation of this report, has revealed the great divergence in the nature of the teaching of graphic methods in engineering colleges and schools throughout the world. The Committee, therefore, felt that some practical results might ensue if information was collected from various sources as to the nature of the teaching in different countries, such as the number of hours devoted to the subject and the kind of teaching given, and also felt that it was possible certain specific recommendations on the subject might be made.

The above examination of the different systems and courses of instruction both in Europe and America reveal the fact that the solution of problems graphically received a certain amount of attention in nearly every engineering course of instruction In England such instruction is given as a rule, in most colleges incidentally, when the subjects of statics, machines, or hydraulics are being dealt with, although recently in some cases special training in graphical methods is being introduced as a part of the course of engineering instruction, in several cases being given as a branch of descriptive geometry. Thus in the Science and Art department, both under the heads of descriptive geometry and also machine drawing, a knowledge is expected of some of the elements of the subject. On the continent of Europe, however, for many years, not only have special courses of lectures been devoted to the teaching of graphic statics as a separate branch of the subject, but there have been a large number of schools in which there are special professors of graphical statics. The reason for this difference is to be found, not altogether, as it is often supposed, in a want of appreciation on the part of English engineers or professors of graphical statics -for it was in England that the germ of such methods was first developed by Rankine, Clerk Maxwell, Fleeming Jenkin, and others -but because the system of appointing professors in the special polytechnics devoted to the allied sciences is there in vogue rather than in England, where one or two chairs of engineering are added to other chairs of the university or university college.

Now, it is instructive to note the general method of instruction indicated in the syllabuses of engineering schools, and which are even more clearly shown in the various text-books on the subject. From these it is clear that the general methods consist of giving certain rules, which may be called general graphic methods, and which apply to addition, multiplication, powers, and extraction of roots, which may be regarded as forming the introductory portion. This is followed by what may regarded as an introduction to statics, in which special stress is laid on geometrical constructions, and the solution of many problems are given which would otherwise be worked out by analysis.

The report then proceeds to discuss the nature of this teaching, and concludes as follows :—It is clear that courses of instruction might be given under the head of Graphical Methods, which might be taught in the same way as descriptive geometry, and which ought, indeed, to be worked in conjunction with that subject. This subject should deal with the construction of such geometrical figures as are important for graphical application. It should also deal with the plotting of results and the general properties of plane curves, as far as the student is able to numerically effect measurements with it, which he can check by calculation. A student should be expected to do his work with great accuracy, and to regard the results he obtains as accurate enough to be useful in practical work, although such examples need not at the time be applied to any practical engineering problems. Thus, for instance, the propositions of projective geometry, so far as the null or focal system is concerned, and the projective properties of bodies, and of the pole and antipolar, might be taught ; but a systematic treatment of the subject of projective geometry is not necessary for engineers. With regard to projective geometry, it may be said that, unless it is desired to study the higher branches of the subject, there is no necessity whatever of a treatment such as Culmann has given in his chapters on the "projective relations between the polygon of forces and the funicular polygon" and the "relation of a system of forces with the focal system, and with curves of the third degree," or with the central axis of a system of forces, or colinear and reciprocal relations of the funicular or force polygon.

There appears to be no reason, therefore, why an elementary course of a general nature, specially arranged so as to include all that an ordinary engineering student requires to know of graphical methods, should not be introduced as a regular subject in engineering schools, and the following arguments may be brought forward in support of this view :—

(1) Although the time-tables of an engineering department are already full, yet it will be found that a course such as that suggested really includes much of what is taught at present in a desultory way, and such a course would obviate some of the teaching given under the heading of "descriptive geometry," so that during one or two terms of a year it might be taken during the same hours as already devoted to descriptive geometry, with possibly one lecture a week, for one term, in the place of the actual lectures in the applied engineering, into which at present graphic methods are often obliged to be introduced for the want of proper preliminary training in the subject by a student. Moreover, the time now devoted in the engineering laboratory for the plotting of curves might be much better occupied in the drawing hall itself in connection with the practice of the plotting and interpolation of curves as a part of the subject of graphic methods, the data obtained from the engineering laboratory affording useful information.

(2) The time spent in such graphical work would be an excellent discipline in accurate drawing for a student, who is often inclined to regard a sketch roughly representing an idea as sufficient for practical purposes. A student should learn for himself that nothing is so easily deceived as the eye. It is quite true, as Prof. Culmann says in the preface of his work, that the constructing engineer will give preference to geometrical solutions wherever an accuracy of results up to three decimals (one-thousandth), which can perfectly well be obtained, is sufficient, for his drawing instruments are always at hand, and drawing is his habitual expression of thought. But such accuracy in drawing is by no means naturally or intuitively acquired, and the student requires training in a course of graphical methods before he would appreciate their value. Moreover, such practice in actually performing the operations, and becoming familiar with the solution, is absolutely necessary, if it is to be expected that a student will really use these problems afterwards in his practical work, as such modifications become extremely puzzling owing to the want of a thorough acquaintance with the methods.

(3) It is not only necessary that a student should be familiar with accurate drawing, but also that he should be familiar with graphical constructions as a means of solving problems. The plan ordinarily adopted in the teaching of statics in conjunction with graphical methods themselves seems expecting too much for the capacity of an ordinary student and the difficulty of getting a class of even intelligent students to correctly solve problems out of the beaten track to the difficulty involved in combining these two things. In the use of ordinary geometry or analytical methods there are separate classes for algebra, analytical geometry, trigonometry, &c., and yet the ideas involved in them are no more difficult than those included in graphical constructions and methods. Graphical methods certainly, therefore, have the same claim to be considered as a separate branch of study.

The following proposition, supported by these arguments, is therefore brought forward :—"That in all engineering schools a separate course in graphical methods of construction may with advantage be introduced which shall deal with such problems as have a practical bearing on mechanical science, and which do not involve applications of any concrete subjects, such as statics and dynamics, *but which may familiarise the student, by means of examples accurately worked out by himself, with methods which he will be afterwards able to apply.*"

It is satisfactory to know that this proposition, which was brought forward at the recent International Congress at Chicago by Prof. Hele Shaw, received the general approval of a very representative body of engineers and professors.

The report concludes with a tabulated statement of the present state of the teaching of graphic methods in Europe and America.

Standard Time in Italy.—According to the provisions of a recent legislative enactment, the railway service of the entire kingdom of Italy will be regulated, on and after November 1st next, by the mean solar time of the 15th meridian east of Greenwich, and the hours will be reckoned from midnight to midnight. This amounts to the adoption of the so-called middle European time, which is one hour in advance of Greenwich, and eleven minutes in advance of the mean solar time of Rome. It is expected that the other public services, and the communities in general, will soon adopt the same system.

STEEL-PLATE PORTRAITS

Of Willoughby Smith; W. H. Preece, F.R.S. (President of the Institution of Electrical Engineers); Michael Faraday; Sir John Pender, G.C.M.G., M.P.; Sir William Thomson, F.R.S. (Lord Kelvin); C. H. B. Patey, C.B.; Dr. John Hopkinson, F.R.S.; Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S.; Prof. von Helmholtz; Prof. W. E. Ayrton; Lord Rayleigh, F.R.S.; Cyrus W. Field; Werner von Siemens; and Sir James Anderson, have been issued as Supplements to "THE ELECTRICIAN."

Copies of these admirably-executed Steel Engravings can be supplied price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price 4s. 6d., carriage paid (U.K.).

SUPPLY AND DEMAND.

The mania among parents and guardians for "putting" their sons and wards "into electric light" has not yet received the natural check which can alone be given by the law of supply and demand. Soon after a demand for electrical engineers had been felt, technical colleges and other institutions sprang up to furnish the supply. These institutions, not contenting themselves with teaching scientific principles, are encouraged by the popular craze for technical education to impart a smattering of trades and handicrafts; and so far has this gone, that some of them boast of private central stations, in which the student is supposed to get an acquaintance with real central-station work. The pendulum must soon begin to swing the other way, when the supply exceeds, in actual quantity, or in apparent quality, the demand, which, though really tending to steadily increase, is practically diminished by over-production. There is generally a time-lag between the application of the law of supply and demand and its result; demand, as a rule, preceding the supply. Especially in the case of the failure of demand and the diminution of supply, this lag brings with it much disappointment. On the other hand, to take at the flood the tide in the affairs of men, and to follow it when it leads on to fortune, is an obvious proceeding. Sometimes a mere fool can ride in to success on the crest of this wave, but when the surge is strong and the bottom is shoaling none but a strong man can fight with the breakers. The scientific plan, and the one adopted instinctively by those who enjoy a business instinct, is to take the wave at about a quarter of a period before the apex, thus taking advantage of the converse time-lag between the rise of demand and the consequent development of supply. Unhappy, indeed, is he who is out of phase with

Digitized by Google

the day, and struggles in the trough of the wave, or, in mathematical language, under the curse of a negative sign.

One of the most recent demands has been that of municipal authorities for consulting engineers. A few men have been having a merry time, and now others, with or without qualifications, are rushing in. The situation is most unfortunate for the municipal authorities, for they confessedly know nothing about electric supply, and too often nothing about their adviser. There is room for many kinds of malpractice, and even fraud, between the extreme cases of absolute incompetence and of concealed connection with contractors, or of actual contracting under another name. Happily the demand for this branch of consulting engineering must speedily decline, because the municipal engineers of the next generation will be expected to add general knowledge of the supply and distribution of electrical energy to their qualifications, and the expensive services of gentlemen who are believed to keep reports in stock, only filling in names and figures for each case, will be dispensed with.

Ten years ago, when the possibilities of electrical engineering as a new branch of the profession were felt, and when its limitations and development could not be foreseen, there were many who, remembering the fortunes made during the railway mania, and the imposing reputations made by sheer luck at that time, and kept up by mere courtesy to-day, thought that electric lighting and the other vague possibilities of electrical developments might lead to such another loud demand. Through various causes, attributed by some to the Electric Lighting Act of 1882, by others to reckless company promotion, and by a small minority to the undeveloped condition of electrical engineering, the demand was but small and the growth of the industry was gradual. Another limitation which might indeed have been foreseen was the sub-division of the profession of electrical engineering into heavy engineering, such as dynamo building, lighter manufactures, instruments and switch work, and the gradual passing of wiring and fittings into the hands of enterprising gas-fitters. While everyone must regret that wiring should be undertaken by decorators and ironmongers who, knowing nothing of the work, rely on the services of a foreman and are kept from doing serious mischief only by the rules of supply companies and insurance offices, this is not due so much to disinclination of busy dynamo makers to bother about wiring and fitting, as to the up-springing of firms who confine themselves to this work. Scores of young men start in twos and threes as general electrical contractors, but practically do nothing but wiring. "Messrs. Dyck, Thomb and Harrie," runs the familiar paragraph, "beg to announce that they have severed their connection with the Brush Company, and have gone into business on their own account, and a £5 note, their offices being in Victoria-street, S.W." It was hardly for this work that parents "put" their sons "into electric light." The very rawness of such firms, as well as the huge bills of extras, have given work for consulting engineers, but this seems to be a temporary phenomenon. A fee to really remunerate the work of a consulting engineer in specifying not only for the quality and mode of wiring, but for the positions of lamps and switches, testing the insulation, and fighting for his client over the extras, must add very materially to the cost of introducing electric light into a house. This branch may perhaps pass into the hands of architects, and no one will indulge in the luxury of a consulting engineer for such work unless he means to hand over himself and his house to the mercies of an architect.

There will, of course, be an "up" for every "down," and it is in no pessimistic spirit that we have endeavoured to forecast a few "downs." Electricity, though no longer in its infancy, is hardly yet in its maturity. A contemporary recently recorded the fact that the alternate-current motor problem had not been solved for three weeks, possibly because inventors, aware of the principle of lag between supply and demand, are waiting until the demand wave definitely rises above zero. The problem of cable telephony and high-speed cable working has been deliberately brought forward to stimulate a demand. Such economic self-induction is well recognised, and the clever salesman is he who persuades a customer to buy something that he does not want. But the abnormal advance of supply in front of demand is associated almost entirely with luxuries, and no one can deny that ocean telephony, even if perfectly feasible and requiring no impracticably expensive cable, would be a mere luxury. But the element of chance comes in, since the luxury must "catch on." This the phonograph has failed to do, and, after many years of obscurity, is appearing among street shows, and finds a pitch between the fat woman and the steam merry-go-round at fairs. A not unlike case occurs when the supply exceeds the demand to a ridiculous degree, as in the invention of arc lamps. Hundreds have been invented at an immense expenditure of ingenuity and money, and about three are really successful, and none perfect. Artificial restrictions have, according to one view, impeded the development of the glow lamp in this country, and, according to others, supported, indeed, by what we hear of most foreign lamps, the immunity enjoyed by monopoly has allowed opportunity for unusual care and skill in the manufacture. The price of the more usual sizes of glow lamps was reduced from three-and-ninepence to one-and-ninepence yesterday, and although this voluntary concession will no doubt relieve the shock, with the expiry of the patent a sudden discharge of accumulated supply may be expected. Oscillations or unstable conditions may be expected to last a twelvemonth or so, and will be watched with interest. A ninepenny lamp is, after all, a trifling matter, equivalent to five per cent. or so on the meter bill; but one more example may be given, where the cost runs to millions of pounds. In this a strong demand exists, and becomes more and more imperative; we allude to electric traction, either on tramways or underground. Hastily-conceived schemes for importing American plant, ready designed, ready made, and warranted to do everything but run at fivepence a car mile, is not the way to develop electric traction. The growth of the demand in advance of the supply is a healthy and really stable condition, and we hope that the curve of demand in electrical undertakings, though necessarily subject to fluctuations, may never fall below its axis.

REVIEWS.

Numerical Examples in Practical Mechanics and Machine Design. By R. G. Blaine. (London: Cassell and Co. 1893.)

One of the most efficient methods of impressing a principle or illustrating a practice, in science, consists in working out numerical examples or problems. As an aid to the lectures, problems serve the useful purpose of thoroughly grounding the student in the exact meaning and relationship of physical quantities and of the terms by which they are expressed; thus etching into his mind the principles, the first general statement of which he receives in the lecture room. As an adjunct to the workshop, the working of problems in leisure hours tends towards uniting the daily empirical practice with theory, and serves to correct the looseness of ideas which mere workshop practice is liable to breed. Problems lie as a connecting link between theory and actual practice,

Digitized by Google

and neither the one nor the other can be fully grasped in all its essential bearings without a certain amount of exercise of this kind. But there are problems and problems. There is the highly differentiated impracticable problem which, with much chagrin, the student meets in certain examination halls, and there is the problem which is designed not to trick, but to instruct. It is to the latter, of course, that our commendations solely relate; but even here we must discriminate. Those who have had considerable experience in conducting problem classes will agree with us that there is a certain indefinable and totally unaccountable catchiness about some problems, which is not to be found with others that, to all external appearances, are of equal value. Some problems go straight to the student's difficulty and unearth it at once; they seem to catch on directly. Others, while dealing with the same facts, appear to be capable of teaching little or nothing. In general, it would appear better to construct a problem so that the mere arithmetical part of it will work out easily, rather than to so select the magnitudes that the student's mind is bewildered in a maze of awkward roots and inconvenient decimal places. A careful instructor will be on the watch to sift out of his problem-book all those examples which do not stand the fire of active service; so that, at the end of several terms, he will possess a refined and tried collection, which will be of the greatest value in driving physical truths home to the student-mind. It is just such a well-tried assortment of problems which we find before us from the pen of Mr. R. G. Blaine. These have all been selected from the best of the problems used in the classes at the Finsbury Technical College. We can strongly recommend them to students, apprentices, and all sorts and conditions of engineers; for they are well arranged, well illustrated, cheap, and handy, and it will be likely there is not a man among us but who will learn something useful from a perusal and practice of them.

It is very rarely that such a book as this is not prepared "to meet the requirements of" certain examinations. The present work, for which Prof. Perry has written an introduction, is quite free from this evil.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 529.)

A little calculation about the Geissler form of pump, with, say, the capacity of the pump bulb equal to that of the lamps being pumped, shows that it should not take very many strokes in order to reduce the amount of air in the lamps to something very close indeed to zero. In practice, however, it takes very considerably longer than the calculation would lead one to expect. The reason of this is twofold. Firstly, the carbon filaments of the lamps occlude gas, which takes time to come out; and, secondly, the air has a way of sticking to the glass, both of the pumps and the lamps. The occluded gases are removed by lighting up the lamps, when the exhaustion has proceeded far enough to make it safe to do so. The current should not be turned on until the vacuum in the lamps appears to be as good as can be obtained. The filaments are brought to a dull red heat only, at first; and gradually, as the gas driven out is pumped away, they are made brighter and brighter until eventually they are brought up to a state of incandescence, equal, at least, to that at which they will be run as finished lamps. When the current is first turned on, it will at once be seen that gas is driven from the filaments by the pump again taking out air. After the full brightness has been reached, the pumping must be continued until the vacuum is again as perfect as possible.

With regard to the gases which come from the filament when it is thus heated by the current, those which come off at the temperature of red heat, and below, are, no doubt, rightly termed "occluded"; that is to say, they have been absorbed by the filament since carbonisation. Those, however, which make their appearance when the filaments are bright are more probably products of the more complete carbonisation of the filaments by the high temperature to which they are subjected by the current.

The other action, which prolongs the time required to perfect the vacuum beyond the theoretical amount, that of the air sticking to the glass of the pump and the lamps, is more difficult to deal with. This air, which appears to adhere as a film to the glass, will come off gradually, but the process is a very slow one. In order to assist it the lamps are heated during the pumping. Unfortunately it is not such an easy matter to heat the pumps, and it is seldom attempted, except in the laboratory. In Fig. 32 on page 528 of last week's *Electrician* a device for heating the lamps is shown. A metal cover is lowered over the lamps, and a Bunsen gas flame is applied below. The lamps can thus be heated to any desired extent up to the softening points of the glass.

In some factories the lamps are attached to the pumps the other way up. This, however, is not so good, as the lamps cannot then be so well heated, as there must of necessity be a hole in the top of the cover allowing of a circulation of cold air.

When the lamps are heated, the air is driven off the glass and is pumped out. Fortunately for the lamp-maker, the removal of the air film from the pump itself, and from the tube leading to the lamps, is of no very great consequence, for the reason that it takes such a long time to come off. It is not necessary to make elaborate arrangements for heating the pumps. If a pump, being perfectly air-tight and in good order, be worked until no more air is taken out, and it be then left to itself for 24 hours, and after that interval be started again, it will be found to again take out air. This air having come off the surface of the glass. It takes some hours for an appreciable quantity of air to accumulate in this way. Although, then, when the pump ceases to take out any more air, and there is still a film of air adhering to the glass, there may be, nevertheless, an exceedingly good vacuum within the pump and the tubes and the lamps. The lamps themselves, having been heated, do not contain an air film, while the air film on the glass of the pump and the tubes takes a long while getting into the vacuous space. The lamps can, therefore, be sealed off before the air film has had time to come off the glass of the pump and spoil the vacuum. The vacuum in the lamps may, therefore, be just as good as though the pumping had been going on for some days, gradually getting rid of the air film in the pump.

When the lamps are sealed off, air is let into the pump before another lot of lamps is sealed on. On account of this the air film in the pump is renewed with each batch of lamps, and is never got rid of. At the British Association meeting in 1890, Mr. Swinburne described a method for sealing on fresh lamps without letting the full atmospheric pressure of air into the pump. Fig. 34 shows the arrangement. The tube A leads to the lamps, and the tube G to the pump. There is a vessel of mercury in connection with the bottom of the tube D, so that when there is a vacuum in the pump and the lamps there is a column of mercury in D reaching to the point C. When a batch of lamps is sealed off, and another lot is to be sealed on, the mercury reservoir below D is lifted sufficiently to cause the mercury in D to rise and fill the bulb B, and, to an equal height, the tube E. A cock in the lower part of D is then turned, thereby cutting off communication with the movable mercury reservoir. Air is then let into the apparatus at the point where the lamps are to be sealed on. The result is that the air entering through A drives the mercury from B up the tube E F, where it will stand at the barometrical height above the level in B. The lamps are now sealed on, and are exhausted through a tube connected to A by a mechanical pump. The mercury column in E F therefore descends until it is nearly level with that in B. The connection between A and the mechanical pump is then sealed up. The cock in D is again opened, and the mercury reservoir is lowered. The mercury, therefore, runs out of B and E to about its former height, C, in the tube D.

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

passa ge is then open between the new lot of lamps and pump which is then set going. In this way the greatest sure of air at any time allowed within the pump can be down to that equal to about half-an-inch of mercury. Such ntrivance would, however, be of little practical use in con tion with most forms of pump, because there is another nnel by which the air-film in the pump is continually main- ted.

There is, however, a far more serious trouble than that of air film to be guarded against in working with mercury ops. It is that of moisture. Any moisture in the pump l make a good vacuum an impossibility. It will be impos- e to obtain an exhaustion of less than the tension of the ter vapour, which is so great that the vacuum obtainable is nearly good enough for a lamp. At the ordinary tempera- e of the air the pressure is equal to that of about half an h of mercury. In order, therefore, to keep the pump dry, re is always a "drying tube," containing some substance ving a great affinity for water, connected to the pump. This e is usually inserted between the lamps and the pump, so to prevent any moisture from the lamps from passing into pump. Calcium chloride, or strong sulphuric acid, have en employed as the drying agent, but the only really effec- e drier is phosphoric anhydride. A tube, or tubes, of is substance (a white powder) are connected, so that

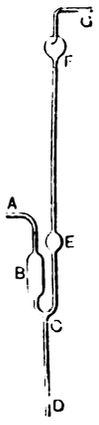

FIG. 34.

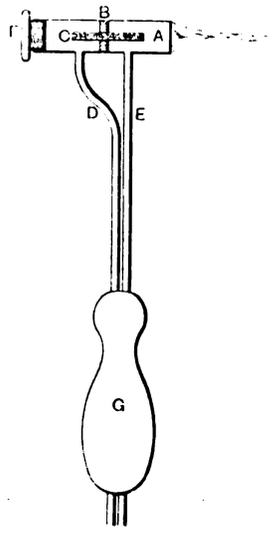

FIG. 35.

he air passing out of the lamps must pass over it. The mps should be as dry as possible before they are sealed o the pump, or the drying tubes will have to be very requently renewed. Between the drying tube and the pump here should be a small bulb containing glass wool, to prevent ny of the powder from being blown round into the pump. The amps should be joined to the pump by fusion. Rubber and ther joints are not to be relied on. In sealing a lamp on to he pump a hand blow-pipe must be used, and on no account nust the lamps be blown into in order to blow out the joint. When glass tubing is softened by heat it always caves inwards, and it is usual in glass-blowing to blow into the tube in order o prevent the passage from being closed up. After a little practice it is quite easy to seal on lamps without having to blow into them. If, however, it is desired that the joints be blown out, the air contained in the pumps and the lamps themselves can be made to do the work. When the lamps are sufficiently exhausted they are sealed off by melting the narrow part of the stem close to the bulb, by means of the pointed blow-pipe flame. The stem of each lamp sealed off is there- fore left on the pump. In sealing on fresh lamps only one of these stems is cut off at a time, so that as soon as the new lamp is melted on there is no outlet for the air in the pump and the lamps. The heat of the joint being made, warms the air within the apparatus, and the air consequently exerts a pressure within, and blows the softened glass at the joint outwards. With a little practice this can be done with certainty to the required extent each time. If several lamps are exhausted at the same time on each pump, there is a good deal of time lost in sealing on each one separately in this way. It is, there- fore, better to cut off the whole of the "fork," to which the lamps are attached, and seal on a fresh one to which the lamps have already been attached. There is then only one joint to be made on each pump, instead of one for each lamp.

In order to do the sealing on easily, it is necessary to have a small and light blow-pipe. Fig. 35 shows one designed by the author for the purpose. It is so small that it can be used in places where there is very little room to work. A is the brass barrel about 2in. long, divided by a partition, B, in the centre. A tube, C, is screwed into B, and forms the air nozzle. D is the air-blast pipe, and E is the gas pipe. The air-jet tube, C, can be adjusted by screwing it in or out with a screw- driver, by taking off the cap F. The pipes D and E pass through a wooden handle, G, and are connected to the air and gas supply. The rubber air and gas tubes are entirely out of the way, and do not impede the manipulation of the blow- pipe as they do when attached to the barrel in the usual way.

Unfortunately, moisture can, and often does, get into the pumps, and seriously interferes with their working in spite of the drying tubes. It gets in along with the air used for rais- ing the mercury. It is naturally most troublesome in damp weather. It gets worked in in exactly the same manner as the air film already described. The trouble is greatest in pumps where the mercury is raised by compressed air. The author has tried passing the air over calcium chloride before it enters the pump reservoir. In damp weather a lot of moisture was absorbed in this way, but it did not entirely prevent the entrance of moisture into the pump. In the case of hand or other pumps where the mercury reservoir is itself lifted, air and moisture might be prevented from entering by having the top of the reservoir entirely closed. The reservoir would then require raising 30in. higher than it otherwise would, owing to the absence of air-pressure on the mercury.

(To be continued.)

LIST OF THE ELECTRICAL PAPERS READ AT THE BRITISH ASSOCIATION.

The following is a complete list of the electrical Papers read and reports presented at the Nottingham Meeting of the British Association :—

THE BRITISH ASSOCIATION AT NOTTINGHAM.

Thursday, September 14th.

The proceedings of Section A were opened in Nottingham to-day by an exceedingly interesting Address by Mr. R. T. Glazebrook, on the ether theory of light in relation to the difficulties which led to its earlier acceptation by Newton. The attendance varied between 100 and 120, according to the phase of the lecture, and when the reading of reports began it fell to less than half that number. At the conclusion of the President's Address a Nemo arose from out the crowd, and requested to be allowed the voice of oratory, which being vouchsafed, he proceeded to a demolition of the ether theory, a proceeding which, however, was nipped in the bud by the outcries of the audience and the veto of the President. Excitement, momentarily raised to a higher than normal pitch, fell to zero before a series of reports, most of which reported nothing save that the Committees wished to be re-appointed and, in many cases, to have a further grant of money. Report stage was thus quickly, if uninterestingly, passed, and the proceedings hurried on to the most valuable and interesting part of the morning's programme, namely, the Paper by Prof. G. F. Fitzgerald on "The Period of Vibration of Disturbances of Electrification of the Earth." Considering the earth firstly as an isolated charged spherical conductor, the period of oscillation of any electromagnetic disturbance caused by a perturbation of the electric charge was calculated. Secondly, considering the fact that there is entirely surrounding the earth a spherical shell of conducting highly rarefied atmosphere, the capacity should really be that of two concentric spheres and much greater than one isolated sphere; a result which, in itself, would considerably alter the period of oscillation. But the proximity of the outside conductor would also alter the self-induction of the system, bringing two inductive current elements near together at each electric disturbance on either sphere. The combined result of the increased capacity and of the decreased self-induction of the system was found to result in a very inappreciable change of the periodic time of the electromagnetic oscillations. A distribution of 80 C.G.S units of charge per square centimetre would be capable of causing 10 per cent. variation of the value of the earth's magnetic force, equal to a magnetic storm of unattained power; but the smaller variation of one-hundredth of H might arise from 8 C.G.S. units per sq. cm. in actual fact. It would be interesting to arrange a large number of needles of various periodicities, so as to get a response to any natural electromagnetic oscillations which might occur, but Prof. Fitzgerald has not yet succeeded in arriving at any definite practical result. Incidentally Prof. Fitzgerald answered the question in the Presidential Address: What is an electric charge? Outside the charged body, he said, there is a stress in the ether; inside the charged body there is a stress in the matter; and the measure of the quantity of the electric charge is simply the measure of the latter stress, the charge being located at the place where one stress ends and the other begins. Prof. Lodge, in the interesting discussion which ensued, observed that he considered such researches should be conducted in a magnetic observatory and not in a physical laboratory, as in the latter place there is a liability to serious magnetic disturbances due to local causes. He also remarked that the supposition of an envelope of conducting material concentric with an atom, or the conception of an atom as electrically equivalent to two small concentric spherical conductors separated by dielectric ether, might be found to explain the discrepancy between the actual period of light vibration of the atom of a heated gas and the theoretical period which that atom should have, assuming it to be equivalent to a simple isolated sphere. In replying to this last point, Prof. Fitzgerald remarked that such an atom would be incapable of producing external radiations on account of any harmonic disturbance of its ionic charge, and that all its actions would lie internally with respect to the outer envelope. The remaining Papers were of an astronomical and optical nature and interest. In section G there were no electrical Papers.

Friday, September 15th.

This was a busy day in both Sections A and G. In Section A the Papers were devoted to electrical and optical theory and to electrolysis. In Section G the Papers were chiefly of interest from a central-station point of view, dealing with mechanical engineering questions. In Section A comments were made on the report on "The Present State of our Knowledge of Electrolysis and Electro-Chemistry." This report states that a comparison of the numerical results of electrolytic observations is rendered difficult from the fact that the data are scattered in various periodicals, and expressed by different observers in units that are not comparable without considerable labour. An exhaustive table, in which are included all the observations, as far as they are known for the metallic salts and mineral acids, has been compiled by Mr. T. C. Fitzpatrick. The data included refer to the strength and specific gravity of solutions, with the corresponding conductivities, migration constants, and fluidities. The chief Paper of the day was read by Dr. Lodge, on the "Connection between Ether and Matter." This Paper, which gave the results of a number of experiments made by Dr. Lodge to discover whether there is any direct mechanical connection between matter and the ether around it, gave rise to a lengthy and interesting discussion. Incidentally, Dr. Lodge made some incisive and caustic remarks on the evils of being too explicit. "The beauty of mathematics," said he, with delightful naivity, "is that it is so vague!" Up to a certain point an equation is perfectly exact, but beyond that point it is capable of varying interpretation. Leaders of scientific thought are often pressed to give some mechanical meaning to their formulæ-theories; and the explanations are twisted by their disciples into distorted ideas, and are pressed altogether beyond the intended limits. A leader tells his disciples—"if he is so fortunate as to have any disciples"—that the ether represented by a certain equation behaves *like an elastic solid*. Forthwith it is published by the said disciples that he said the ether *is* an elastic solid, and so on.

The apparatus designed by Dr. Lodge consisted of two flat circular discs of tough steel, one yard in diameter, rigidly fixed in two horizontal planes to a vertical spindle, at a distance of 1in. apart. This apparatus was set in very rapid rotation—in most instances the speed was as high as 3,000 revolutions per minute—and while thus in motion the gap between the discs was traversed circumferentially by two equal rays of light, one ray passing round in the direction of motion of the discs, the other in the reversed direction. By an arrangement of plane mirrors it was possible to make each of the two rays of light

Digitized by Google

pass five or six times round the circumference of the discs in the air gap between them; but usually only three rotations of the light was arranged. The interference bands formed by the superposition of the two rays were directed upon a screen, and the effect to be observed was whether any displacement of these bands took place when the discs were first at rest and then set in rapid motion; and further, whether a reversal of the motion of the discs would reverse the displacement of the interference bands. The errors to be eliminated might arise from the intense air pressure on the mirrors, set up by the whirling motion, by the heating of the air and discs, and by the actual displacement of the ether due to the motion set up in the air in the gap. The first was eliminated by the use of glass windows in a screen of metal completely enveloping the rotating discs. The last was corrected by an application of Fresnel's formula—

$$1 - \frac{1}{\mu^2},$$

which gives the proportion of the ether set in motion by the moving air, and which in this case came out to $\frac{1}{200}$th of the speed of the discs. When every effect had been traced to its probable source, the resulting deduction might be drawn that there is no mechanical connection between the ether and the matter which it may surround; that, in fact, the motion of gross matter does not set the environing ether in motion with it. Stress-energy belongs to the ether; inertia-energy belongs to matter; and no mechanical interchange of energies takes place. Every action may be considered to commence and to terminate on lumps of matter—ordinary gross matter; and there is no line of stress leaving any portion of matter and sticking out into the ether without coupling itself to some other portion of matter. In other words, Newton's third law of motion relates to two portions of matter if it relates to one. Such is the gist of the conclusion arrived at by Prof. Lodge.

In the discussion which followed this Paper Prof. Hicks remarked that he considered the negative results quite inconclusive, because there was no evidence to show that the dics would not require a very much longer time than had been given in order to stir up the ether. The experiment had been conducted after several hours' motion of the discs. What was there to prove that the ether might not require hundreds of years? In reply, Dr. Lodge said that if the question of time must enter into consideration, there was no reason to suppose that three hours was better than three minutes, and that if the effect was not practically instantaneous it might take many thousands of years. All our experience of the ether would lead up to suppose it would readily take up such disturbances. He had observed the interference bands close up to the image of the discs, and had detected no trace of displacement. Prof. Fitzgerald said that he did not consider that there was never a mechanical action between matter and the ether, such as would be contradicted by the stated interpretation of the law of action and reaction. He mentioned several cases where an action of matter on the ether is unaccompanied by any reaction of a second portion of matter, such, for example, as the stress between the reflected light and a parabolic mirror, sending light out into interstellar space. Incidentally, Prof. Fitzgerald introduced a theory of what he called "corkscrewedness." A displacement current in a dielectric might be illustrated by a rotating corkscrew, in which there is both rotation and an apparent transition of something along the length of the corkscrew. Magnetic force might be explained as a change in the 'corkscrewedness" of the ether; if the spirals of the corkscrew were to swell out or to diminish to different radius there would be the analogue of a magnetic force. Steady currents in conductors might be explained without any variation of the "corkscrewedness" on account of the effect taking place in a closed conducting path. The necessary closed condition of a magnetic flux and the unnecessity of closedness of an electric flux would seem to point to the possibility of the magnetic effect being a continuous displacement along the line of the flux, and the electric effect being rotary. Dr. Lodge pointed out that, inasmuch as magnetic lines were necessarily closed, there was no ground for stating that no displacement takes place along their length.

In the absence of Lord Kelvin, two Papers entitled respectively "On the Piezo-Electric Property of Quartz," and "On a Piezo-Electric Pile," were read by Lord Rayleigh. These Papers deal with a potential difference set up in a dielectric or a pile of dissimilar metals by means of unequal distribution of pressures. A Paper by E. H. Barton dealt with some interference effects somewhat analogous to Newton's Rings, but exhibited by waves in wires. And a Paper by G. H. Yule dealt with the behaviour of thin layers of electrolytes when used with respect to waves of low frequency as thin plates are used with respect to waves having the frequency of light. The optical behaviour of quarter-wave and half-wave plates, and thin plates generally, was shown to take place.

In Section G the Papers of electrical interest discussed the well-worn subjects of "Refuse Destructors and Thermal Storage," and on the "Druitt-Halpin Scheme." No points of importance were raised in the discussions.

Saturday, September 16th.

Very few of the sections met for reading Papers on this day. Section A devoted itself to the discussion of matters of pure mathematics, such as "Agreeable Numbers," with disagreeably complicated theories attached to them, and to other questions of a mathematical nature. The "Note on the Magnetic Shielding of Two Concentric Spherical Shells," by Prof. Rücker, may perhaps be the foundation of a practical system of shielding. The two Papers by Prof. Fitzgerald, the one on "Equations for Calculating the Effect of a Long Tube as a Magnetic Screen," and the other on "Equations for Calculating the Effect of a Hertzian Oscillation on Points in its Neighbourhood," are beyond the radius of activity of most electricians, and their chief interests were mathematical. A considerable portion of the audience took this opportunity of wandering into the chemical and physical laboratories, where a good show of interesting apparatus was provided. Among the exhibits we noticed a number of instruments lent by the Cambridge Scientific Instrument Company, including a Callender electrical pyrometer. This consisted of a resistance box, batteries, an indicator, and a long steel tube containing a platinum thermometer, for insertion into furnaces or other places where a high temperature is to be measured. This firm showed a "tromometer," an instrument for recording earth tremors by means of a mirror and a beam of light. Several photographs of flying bullets were shown by Prof. Boys, and inductoscripts by the Rev. F. J. Smith. This photographic process is now of some interest, as it has been brought to a point at which it promises to be of practical value as a printing process. Messrs. Nalder Brothers had on view a number of instruments, including an optical bench and a high-resistance galvanometer made to Dr. Oliver Lodge's design, together with other apparatus which we have already described. Sir David Salomons, Messrs. Pyke and Harris, and Mr. Paul contributed specimens of electical apparatus.

Monday, September 18th.

Electrical interests were mainly concentrated in the proceedings of Section G on this day. In this section the list of Papers down for reading was headed by a short Paper by Mr. Gisbert Kapp, on "The Relative Cost of Conductors with Different Systems of Electric Power Transmission." The chief point in this communication was to show the fallacy of supposing that the use of a combined three wire return in two-phase alternate current transmission, instead of four wires in two separate circuits, will give any economy of copper in the mains. The author pointed out that, in the first place, there would normally be a current 40 per cent. greater in the third wire than in either of the other wires; but that, worse than this, the fluctuation of pressure in these other wires, resulting from tying the two circuits together, must necessarily put a great strain on the circuit, and would therefore limit the working pressure. When the limits of safe pressure in the mains alone were considered — the rest of the plant being assumed capable of supporting the limit—it was found that the relative costs of copper in the mains was as follows, mains for continuous current being taken at 100:—

Single phase, two wires ...	200	Double phase, three wires...	290
Double phase, four wires...	200	Three phase, three wires ...	150

Digitized by Google

This result shows greatly in favour of the three-phase three-wire system of transmission, at least, insofar as the power has to be transmitted in bulk and not distributed. Although all these figures for alternating currents are higher than the one for continuous currents with two wires, yet the fact that it is impracticable on other grounds (commutator flashing, &c.) to use very high continuous pressures will lead to the conclusion that the best system in point of view of economy of copper is the three-phase three-wire system; and that coupling the two return wires in the two-phase four-wire system will not cause a saving in copper, but increased expenditure.

In the absence of Mr. A. T. Snell, his Paper on the "Utilisation of Water-Power by Electricity" was read by Prof. Robinson. In the discussion which resulted Prof. Unwin observed that the statement that water power was, on favourable mill sites, dearer than coal or fuel of any kind was wrong; and that in such cases it would probably be found that the expenses were almost nominal, as low as £1 per horse-power per year, for example. Mr. Lupton said he thought that this country abounded in water mills, many of which, however, had been abandoned. Several speakers commented on the necessity of stating the actual costs of an English water-power plant, such as Mr. Snell advocated. Mr. Carter criticised the conditions of average English mill sites, and remarked that they were not in general financially utilisable, when the great prime cost of the plant was considered. English conditions generally resulted in inefficient working. The President called attention to the prospect of exhaustion of the coal measures (if the strike does not last too long), and observed that we should then have to depend on water-power and wind-power. He suggested that instead of inefficient chemical storage cells it might be better to set our dynamos to decompose water and compress the hydrogen and oxygen in steel cylinders at a great pressure.

The third Paper dealt with a "New Form of Variable Power Gear for Electric Motors," invented by Mr. W. Worby Beaumont. This is a modification of the gear described in *The Electrician*, Vol. XXX., page 564. While Mr. Kapp thought that the invention was mechanically practicable, Prof. Hele-Shaw remarked that his experiences of epicyclic gear in other applications were not sufficiently happy to allow him to recommend it, and suggested that another form of gear might be incorporated in Mr. Beaumont's mechanism with good results. Mr. Carter considered the period of starting mentioned by Mr. Beaumont as being probably much shorter than would be actually experienced with a change in velocity ratio so great as that proposed. He also pointed out that the use of a higher ratio on up gradients would necessarily result in greatly reduced speed, if the speed of the motor was to remain sensibly constant.

The next Paper was read by Mr. W. B. Sayers, and dealt with his ingenious form of armature winding, and with the joint invention of his brother and himself for regulating feeders on a three-wire continuous-current system. A Paper by Mr. E. Payne, on a "Mechanical System of Electric Conductors," in which the use of fireproof mains was described, concluded the session for the day.

In Section A the meeting was principally concerned with the apparatus and methods of teaching physics in schools.

Tuesday, September 19th.

The proceedings of Section A opened on Tuesday with the report of the Electrical Standards Committee, which was read by Prof. Carey Foster. The unit ohm is defined as the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14·4521 grammes in mass, of constant cross sectional area, and of a length of 106·3cms. The relation between the B.A. unit and the ohm is such that 1 B.A. unit equals 0·9866 ohm. A table of tested coils is given in the report. The committee was reappointed, with a grant of £25. Following this report came an allied Paper by Prof. Viriamu Jones "On Standards of Low Electrical Resistance." Prof. Jones advocated the direct determination of low resistance from an absolute method, known as the Lorenz method, by means of mutual induction with currents of known frequency; and he considered that low resistance standards might be more accurately derived in this way than by derivation down from a unit ohm. He had, however, encountered some difficulty in regard to the electrically propelled tuning fork, as he found that its frequency was liable to a small settled change if it was stopped and restarted. Prof. Lodge considered that the electrically propelled tuning fork should be compared with a free fork both at the beginning and the end of the test; he had not experienced any settled change of frequency in the former, as in all his experiments he had been careful to avoid stopping the fork. Prof. Jones replied that in the present instance it was impossible to avoid stopping the electrically propelled fork. Mr. Glazebrock considered that it might be well as a theoretical standard to adopt the expensive and complicated mutual induction method advocated by Prof. Jones; but that for all practical purposes of a standard, he preferred to recommend the mecury column, as being much more easy of determination.

Mr. F. H. Nalder described the Carey-Foster apparatus, which was illustrated in our report of the meeting of the Physical Society on June 23rd.

Prof. Oliver Lodge described a new galvanometer for physiological research; and a discussion on methods of increasing the sensitiveness of galvanometers followed.

Prof. Lodge made a "Supplementary Note on the Ether," being some thoughts suggested by a criticism on his Paper on Friday. Mr. Cowper Ranyard had proposed to him the difficulty that, if matter exerts no mechanical action on ether, it is not easy to explain the action of dust particles in polarisation of light. Dr. Lodge observed that the action of the dust particles was not mechanical but electrical. Lord Rayleigh observed that there was no more difficulty in reality in connection with the action of dust than in the action of any refracting medium, and that if the one optical effect was mechanical so would be the other. Excitement was momentarily raised by a clamour for an exact definition of the distinction between mechanical and electrical action; which definition, however, neither Prof. Lodge nor any other *savant* seemed able to give, save that there *was* a difference, and that "electrical" meant just what everyone meant by electrical. The crux of the matter seemed to exist in the necessity for exact definition of terms.

In the absence of Mr. A. B. Basset, his Paper "On the Publication of Scientific Papers" was read by Mr. Larmor. The Paper criticised the formation of a central organ, and advocated supplying each author with a large number of free copies of his Paper, and the development of some existing organ, such as *Nature*, into a sort of compendium of abstracts of physical Papers. It also recommended the co-operation of the various scientific societies for the publication every three or four years of a digest of Papers. Mr. Swinburne remarked that the present system was admittedly and undoubtedly bad, that indexes only gave one a list of Papers which, very often, it was difficult or impossible to procure, that journals followed one another like sheep in the matter of publishing and re-publishing again and again some chance Paper, while better Papers were often neglected by them all, and advocated sending Papers to the Physical Society, which supplied authors with a large number of free copies of their Papers. Very few of those present could have heard Mr. Swinburne's delightful remark after taking his seat: "The best way," said he, *sotto voce*, "would be to send round a monthly post-card containing all that is of any use in physical science for the month." Prof. Fitzgerald objected to indexing, because an index only gives one a stone when one is crying for bread; abstracts are better because one gets a little bread with the stone. To expect the proprietor of a successful journal to give up his interests in order to "further science" by putting into his Paper all the physics of the time, would be like asking a man to walk out of his house in the cause of science. Lord Rayleigh announced that a committee of the Royal Society with an open mind was being appointed for the consideration of the matter.

In Section A a Paper was read by Prof. J. J. Thomson on "A New Form of Air-Pump."

Wednesday.

There were no electrical Papers down for reading in either Section A or G on Wednesday.

ON THE PIEZO-ELECTRIC PROPERTY OF QUARTZ.*

BY LORD KELVIN.

In the present communication we shall consider only a perfect hexagonal prism. The sides of the prism may be, and generally are, unequal in nature; but the angles are all exactly 120deg. We have three planes of symmetry, which for brevity I shall call the diagonal planes, being planes through the opposite edges of the prism. We have also three other planes of symmetry, which for brevity I shall call the normal planes, being planes perpendicular to the pairs of parallel faces.

In the brothers J. and P. Curie's beautiful instrument for showing their discovery of the piezo-electric property of quartz, a thin plate of the crystal about half a millimetre thick, I believe, is taken from a position with its faces parallel to any of the three normal planes of symmetry, its length perpendicular to the faces of the prisms, and its breadth parallel to the edges. The sides of this plate are, through nearly all their length, silvered by the chemical process to render them conductive, and are metallically connected with two pairs of quadrants of my quadrant electrometer. In an instrument which has been made for me under Mr. Curie's direction, the silvered part of the plate is 7cm. long and 1·8cm. broad. A weight of 1 kilogramme, hung upon the plate placed with its length vertical, causes one side to become positively electrified and the other negatively.

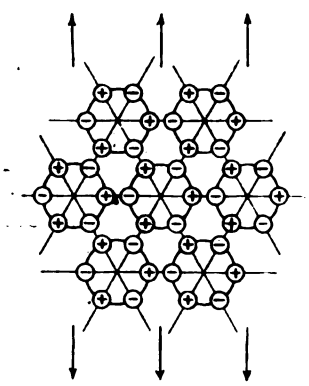

FIG. 1.

Electric eolotropy of the molecule, and nothing but electric eolotropy of the molecule, can produce the observed phenomena. The simplest kind of the required electric eolotropy which I can imagine is as follows:—For brevity, I shall explain it in relation to the chemical constitution which, according to present doctrine, is one atom of silicon to two atoms of oxygen. The chemical molecule may be merely SiO_2 for silica in solution, or it may consist of several compound molecules of this type, grouped together; but it seems certain that in crystallised silica (in order that the crystal may have the hexagonally eolotropic piezo-electric property which we know it has) the crystalline molecule must consist of three SiO_2 molecules clustered together, or must be *some* configuration, three atoms of silica and three double atoms of oxygen combined.

The diagram (Fig. 1) shows a crystalline molecule of this kind surrounded by six nearest neighbours in a plane perpendicular to the axis of a quartz crystal. Each silicon atom is represented by a + (plus), and each oxygen double atom by − (minus). The constituents of each cluster must be supposed to be held together in stable equilibrium in virtue of their chemical affinities. The different clusters, or crystalline molecules, must be supposed to be relatively mobile before taking positions in the formation of a crystal. But we must suppose, or we may suppose, the mutual forces of attraction (or chemical affinity) between the silicon of one crystalline molecule and the oxygen of a neighbouring crystalline molecule to be influential in determining the orientation of each crystalline molecule, and in causing disturbance in the relative positions of the atoms of each molecule, when the crystal is strained by force applied from without.

* Abstract of a Paper read before Section A of the British Association, and to be published in full in the *Philosophical Magazine*.

Imagine now each double atom of oxygen to be a small negatively electrified particle, and each atom of silicon to be a particle electrified with an equal quantity of positive electricity. Suppose now such pressures, positive and negative, to be applied to the surface of a portion of crystal as shall produce a simple elongation in the direction perpendicular to one of the three sets of rows. This strain is indicated by the arrow-heads in Fig. 1, and is realised to an exaggerated extent in Fig. 2.

This second diagram shows all the atoms and the centres of all the crystalline molecules in the positions to which they are brought by the strain. Both diagrams are drawn on the supposition that the stiffness of the relative configuration of atoms of each molecule is slight enough to allow the mutual attractions between the positive atoms and the negative atoms of neighbouring molecules to keep them in lines through the centres of the molecules, as Fig. 1 shows the undisturbed condition of the system, and Fig. 2 for the system subjected to the supposed elongation. Hence two of the three diameters through atoms of each crystalline molecule are altered in direction, by the elongation, while the diameter through the third pair of atoms remains unchanged, as is clearly shown in Fig. 2 compared with Fig. 1.

Remark, first, that the rows of atoms perpendicular to the direction of the strain are shifted to parallel positions with

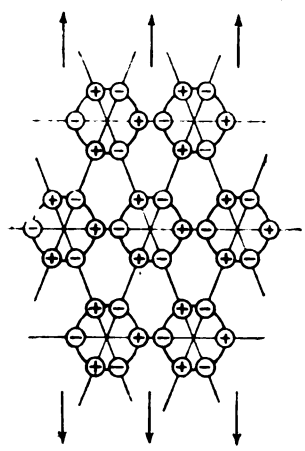

FIG. 2.

distances between the atoms in them unchanged. Hence the atoms in these rows contribute nothing to the electrical effect. But, in parallel to these rows, we find two pairs of atoms whose distances are diminished. This produces an electric effect which, for great distances from the molecule, is calculated by the same formula as the magnetic effect of on infinitesimal bar-magnet whose magnetic moment is numerically equal to the product of the quantity of electricity of a single atom into the sum of the diminutions of the two distances between the atoms of the two pairs under consideration.

Instead of the silicon atoms marked + in the diagram let us substitute globes of polished zinc; and instead of the double-oxygen atoms marked − let us substitute little globes of copper well oxidised (polished copper, heated in air till it becomes of a dark slate-colour). Let us suppose all the six atoms of each compound molecule to be metallically connected, and all the molecules insulated from one another. We are not concerned with conceivable permeation of electricity by conductance through the crystal; and therefore we must suppose the total quantities of electricity on each crystalline molecule to be zero. Let the circle of each compound molecule in the diagram be a real exceedingly thin stiff ring of metal, no matter what kind of metal, and let each of the six atoms be a bead (a perforated spherule), whether of zinc or of copper, moving frictionlessly on it. Thus we have, in idea, a working model of an electrically eolotropic crystalline molecule.

Consider now two simple elongations in the direction shown by the arrow-heads A in Fig. 3. These two elongations produce electro-polarisations with axes and signs indicated by *a a* and *b b* respectively. The resultant of our present two simple elongations is clearly a single simple elongation in the

Digitized by Google

line K′ O K, bisecting the angle between them, and of magnitude equal to $\sqrt{}$ three times the magnitude of each of them, as is easily proved by the elementary geometry of strain. Hence an elongation in the direction K′ O K does not produce zero of electric effect. On the contrary, elongation in the line K′ O K produces an electro-polarisation which is the resultant of the equal polarisations indicated by $a\,a$ and $b\,b$, which, as it bisects the angle b O a, is in a line inclined at 45deg. to O′ K, the line of the elongation. In fact, simple elongation in any direction perpendicular to the principal axis of a quartz crystal produces electro polarisation; and it is only when the lines of two simple elongations are coincident with one another, or are perpendicular to one another, that the resultant of their electro-polarisations can be zero.

A most important contribution to knowledge of the electric properties of crystals has been made by Röntgen, and by Friedel and J. Curie, in independent investigations proving that the irregular electrifications of the corners of quartz crystals, which had been observed by many observers as consequences of heatings and of returns to lower temperatures, are wholly due to mechanical stresses developed by inequalities of temperate in different parts of the crystal. Those phenomena are therefore truly *piezo electric*, and are not at all "pyro-electric" like the electric property of tourmaline which is due to change from one temperature to another, each the same throughout the crystal. The very important and interesting discovery thus made by Röntgen and by Friedel and Curie, is, as they have pointed out, available also to explain the perplexing and seemingly paradoxical statements regarding positive

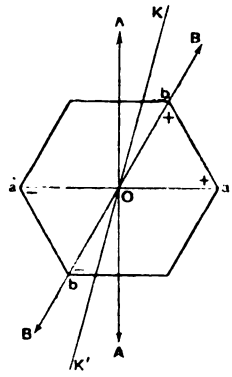

Fig. 3.

and negative electrifications of corners and hemihedral facets at opposite ends of the four long diagonals of crystals of the cubic class, and of cubes of boracite, which had been given by previous observers and writers, and which have not yet disappeared from elementary treatises on Mineralogy, Electricity, and General Physics.

ON A PIEZO-ELECTRIC PILE.*

BY LORD KELVIN.

The application of pressure to a voltaic pile, dry or wet, has been suggested as an illustration of the piezo-electric properties of crystals, but no very satisfactory results have hitherto been obtained, whether by experiment or by theoretical considerations, so far as I know. Whatever effects of pressure have been observed have depended upon complex actions on the moist, or semi-moist, substances between the metals and electrolytic, or semi-electrolytic and semi-metallic, conductances of the substances. Clearing away everything but air from between the opposed metallic surfaces of different quality, I have made the piezo-electric pile which accompanies this communication. It consists of 24 double plates, each 8 cm. square, of zinc and copper soldered together, zinc on one side and copper on the other. Half a square centimetre is cut from each corner of each zinc plate, so that the copper square is left uncovered by the zinc at each of its four corners. Thus each plate presents on one side an uninterrupted copper surface, and on the other side a zinc surface, except the four uncovered half-square centimetres of copper. A pile of these plates is made, resting one over the other on four small pieces of india-rubber at the four copper corners. The air-space between the opposed zinc and copper surfaces may be of any thickness, from half a millimetre to three or four millimetres. Care must be taken that there are no minute shreds of fibre or dust bridging the air-space. In this respect so small an air-space as half a millimetre gives trouble, but with three or four millimetres no trouble is found.

The lowest and uppermost plates are connected by five wires to the two pairs of quadrants of my quadrant electrometer, and it is generally convenient to allow the lowest to lie uninsulated on an ordinary table and to connect it metallically with the outer case of the electrometer.

To make an experiment (1) connect the two fine wires metallically, and let the electrometer needle settle to its metallic zero.

(2) Break the connection between the two fine wires, and let a weight of a few decigrammes or kilogrammes fall from a height of a few millimetres above the upper plate and rest on this plate. A startlingly great deflection of the electrometer needle is produced. The insulation of the india-rubber supports and of the quadrants in the electrometer ought to be so good as to allow the needle to come to rest, and the steady deflection to be observed, before there is any considerable loss. If, for example, the plates are placed with their zinc faces up, the application of the weight causes positive electricity to come from the lower face of the uppermost plate, and to deposit itself over the upper surface of plate and weight and on the electrode and pair of quadrants connected with it.

* Abstract of Paper read before Section A of the British Association.

THE AUTOMATIC BALANCE OF RECIPROCATING MECHANISM.*

BY W. WORBY BEAUMONT, M.INST.C.E.

In this Paper the author pointed out that in most cases of vibration in machinery, whether of rotary or reciprocating forms, the vibration was due to the restriction of the motion which would naturally occur if the nominally stationary parts were free to act under the influence of the disturbing force. To bring about such restriction, and to prevent the movement of the stationary parts, it is usual to balance the moving parts with care, and in most rotating mechanism this can be done with success. It is, however, very difficult in reciprocating mechanism, and in many cases cannot be achieved. The push and pull imparted to and causing reciprocation in the thing to be moved, is equally but oppositely imposed on that which transmits the push and pull. The latter has, therefore, to be so constructed that it can oppose the movement which the operative force tends to bring about.

When the mechanical means adopted consist of a crank, or the like, and connecting rod, it becomes necessary to balance the crank and connecting rod, and often to make the so-called balance-load kinetically superior to the load balanced; in other words, to make the inertia of the balancing parts greater than that of the parts balanced, the excess representing part of that of the reciprocating thing to which motion is communicated. This practice sometimes improves the working of the machinery, but it involves framing of great strength, and mechanism with large bearings and great accuracy of fitting, and does not materially reduce the vibration set up in buildings or floors containing the machinery.

It was shown in the Paper that troubles brought about by this vibration might be completely avoided, and that at the same time the strength, cost, and power hitherto necessary might be all reduced by completely reversing the usual proceeding. The author showed that the cause of this vibration might be employed to effect the working of the reciprocating machinery. Instead of balancing operating parts he purposely puts them out of balance, and instead of attaching them to

* Abstract of a Paper read at the British Association in Section G.

Digitized by Google

the fixed or stationary parts he attaches them to the moving part. In this way the unbalanced motor parts are automatically balanced by setting up as much motion in the thing to be moved as is necessary to absorb the inertia of motion or the momentum of the unbalanced thing in every part of its path. All vibration of the supporting parts is thus avoided, and that which usually sets up vibration is converted into a vibromotor. The Paper was illustrated by working models.

SELF-EXCITING ARMATURES FOR CONTINUOUS-CURRENT DYNAMO ELECTRIC MACHINES AND COMPENSATORS FOR LOSS OF PRESSURE IN FEEDERS OF ELECTRIC SUPPLY SYSTEMS.*

BY W. B. SAYERS.

The object of this Paper is to bring before your notice a new construction of continuous-current dynamo machine, in which that portion of the winding of the armature which for the time being is not subject to the inductive action of the magnetic field is utilised. (1) To entirely produce the requisite flux in the magnetic system. (2) To reinforce the flux produced by other means, such as shunt coils. These conditions are attained practically by the use of a device by which it becomes practicable to fix the diameter of commutation of the armature in the necessary position relatively to the neutral diameter to produce this result. The device referred to, and the mode of its action, was described by the author in a Paper read before Institution of Electrical Engineers on May 11th last, and which will be found in No. 107, Vol. 22, of the *Proceedings* of that Society.

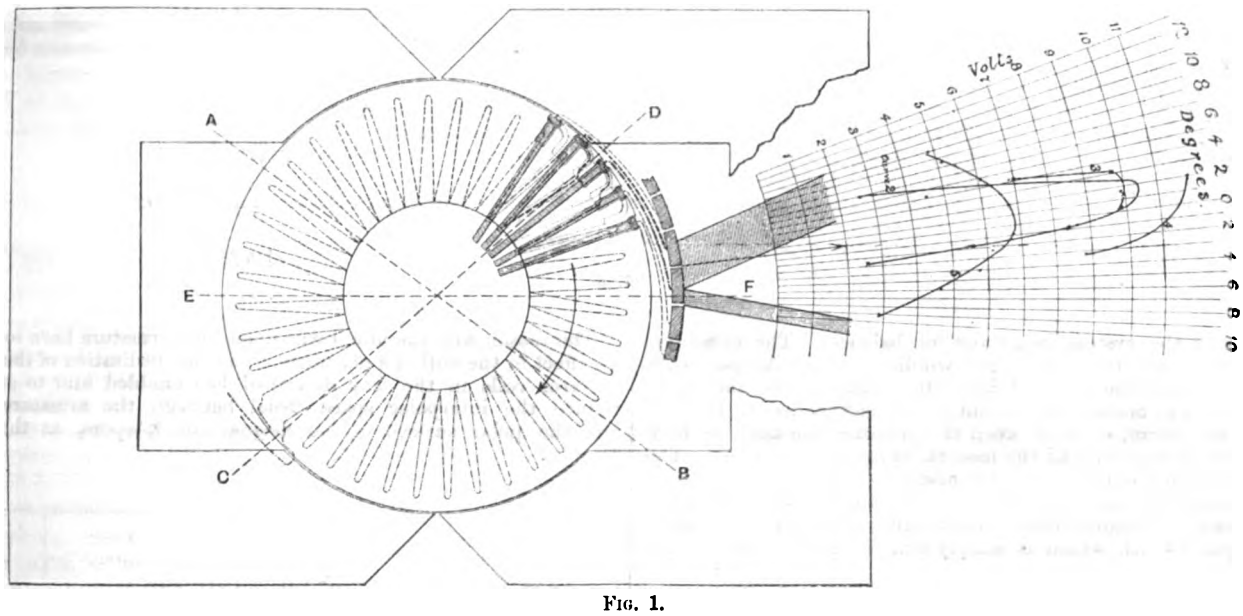

FIG. 1.

Fig. 1 represents diagrammatically a machine in which, in addition to the E.M.F., the magnetic flux is entirely produced by the armature winding. The portions of the winding lying at any time between A and D and C and B are generating E.M.F. while the current in the portions lying any time between A and C and B and D provides the necessary magnetising force. The condition under which this result is attained is that the current enters and leaves the armature at points approximately on the diameter C D, the direction of rotation being that indicated by the arrow. Those familiar with dynamo electric machinery will observe that the diameter C D is angularly displaced relatively to the diameter E F, in a contrary direction to that which has hitherto been the case in practice.

Consider an ordinary series-wound dynamo. Let the connections between the field coils and the armature be changed so as to send the current through the field coils in the opposite direction to that intended, the result would be that the machine would not excite, for the reason that any current generated by the armature would reduce the magnetisation of the system instead of augmenting it. When the diameter of commutation is situate in front of the neutral diameter, which is the case in ordinary practice ; that is, between the neutral diameter and A B (Fig. 1), the effect of the portion of the armature winding lying between the diameter A B and such diameter of commutation is of the same character as that of the field coils of the series machine when they are coupled up in the wrong direction ; that is, it tends to reduce the magnetisation of the system. But shifting the diameter of cummutation backwards proximately to the position A, B, is equivalent to changing the connections of the series coils back to the correct relation to the armature, when they tend to build up or augment the magnetisation of the system instead of to diminish it. In the armatures of the machines as constructed, the connections between the armature winding and the commutator are brought over the core of the armature in such a position, relatively to the points in which they are connected to the winding, that those carrying the momentary current as they pass the brushes are behind the diameter of commutation ; thus, by properly setting the brushes, the connections to the commutator are just under the tip of the pole-piece which is behind the neutral diameter, at the time when the momentary current passes through them to the brushes, while the diameter of commutation is a little in front of this position.

Under these conditions the section of the armature which is passing through the diameter of commutation having passed out of the intense part of the magnetic field, can be effectively reversed (or commutated) by the differential inductive action of the field upon the commutator connections.

It is evident that in a machine such as we are considering any movement of the brushes will alter the number of turns of the armature winding which are effective in magnetising the system, and thus vary the E.M.F. of the machine. In Fig. 1 some curves are given showing the performance of the machine with the brushes in different positions. If the pointer drawn through the larger brush is supposed to move with the brushes, while the curves remain stationary, the pointer will indicate the E.M.F. which would be generated :—In the case of curve 2, when running at the speed of 850 revolutions per minute, with an external resistance in circuit of 0·03 ohm ; curve 3, with speed 1,000 revolutions per minute, and external resistance 0·038 ohm ; curve 4, with one turn of series-winding around each keeper, speed 1,000 revolutions and external resistance 0·045 ohm ; and curve 5, when a constant current of 200 amperes is forced through the armature, with speed 1,000 revolutions per minute.

The machine which is illustrated in Fig. 1 was designed for, and is now in use as, a compensator, for the loss of pressure in the feeders connecting the new Midland Hotel with the Midland Railway Company's generating station at Bradford. The machine is situated in the engine-room, and is coupled direct to a shunt-motor and driven at a constant speed, and the main current of the hotel is passed through the armature. Now the loss of pressure in the feeders for direct-current supply is proportional to the current flowing, as is well known, and on referring to Fig. 2, which is the characteristic of the machine, it will be seen that the E.M.F. generated is almost exactly proportional to the current throughout the range of values given. Thus, the machine being properly related to the resistance of the feeders, the loss of pressure caused by whatever current is flowing is exactly compensated.

The author, in conjunction with his brother, Mr. J. Sayers, of Derby, has recently designed and constructed, at the works of

* Paper read before the British Association in Section G.

Digitized by Google

Messrs. Mavor and Coulson, Bridgeton Cross, Glasgow, two sets of compensators, having self-exciting armatures, for the Midland Railway Company's electric lighting station at Derby. The problem here was not so simple as that at Bradford. The three-wire system being in use at Derby, it became necessary to provide against the disturbance produced by the loss of pressure in the so-called neutral wire when a current is flowing in it, owing to the two sides of the system being out of balance. The difficulty, however, was met by providing a winding on the keepers connected in series with a neutral wire, the winding being put on in such a way as to modify the amount of pressure added to the two sides of the system, so as to keep the pressure constant on both sides at the distant end of the feeders under all conditions. The photograph represents one of these machines.

Mr. Swinburne has pointed out to the author that with his device a motor can be designed having no winding whatever on the main moving part, which would be simply a mass of iron; this would involve the use of revolving brushes, but as there would be no necessity of shifting the diameter of commutation with varying load, there would be no objection whatever to this.

The advantage of such a motor for tramcar work will be readily appreciated.

I pass now to machines in which the idle armature coils—idle that is as regards producing E.M.F., are utilised to produce on a shunt machine the same effect as series coils on the magnets would have, that is, to keep the pressure constant with varying load. Figs. 3 and 4 are characteristic of such machines, which will be self explanatory, I need only call particular attention to curve 1 Fig. 4, which represents the performance of the machine when the brushes are set with a forward lead in the ordinary way, and the idle armature coils exercise their up to the present usual action of pulling down the magnetisation.

FIG. 3.

The reason why the idle turns upon the armature have so large an effect in the author's machines is that his utilisation of the commutator coils in the way described has enabled him to greatly reduce the interpolar space usual between the armature core and the polar surface of the magnets or keepers, as the case may be.

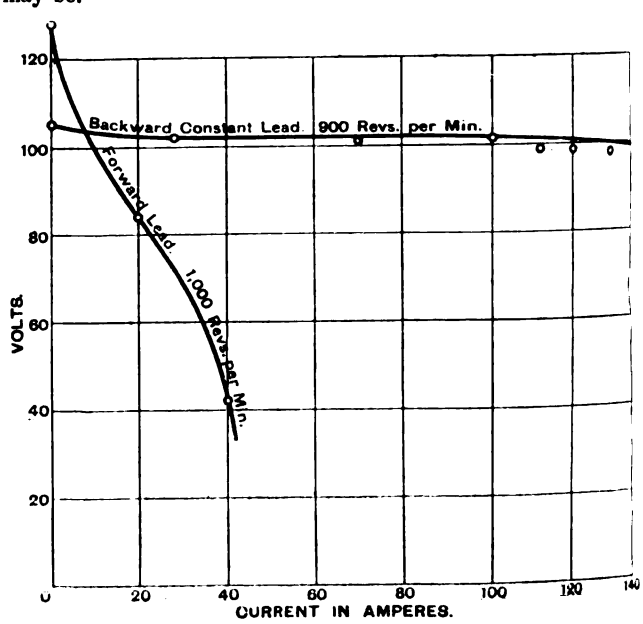

FIG. 4.—10¼ by 12 Dynamo. Design No. 16. Machine No. 324.

The effect of reducing this space is to reduce the magnetising force necessary, but as the number of idle turns are not reduced they become of very much greater importance. As a result of the reduction in magnetising force required the author is able to reduce the weight and cost of dynamo machines to a considerable extent. To show this an illustration is appended, taken from the appendix to the Paper already referred to, read before the Institute of Electrical Engineers.

HALIFAX AND BERMUDAS CABLE COMPANY (LIMITED).—The fourth annual meeting was held on Wednesday at the offices, 33, Old Broad-street, E.C., when the Directors' report and the balance-sheet were adopted unanimously. The result of the working for the year ended June 30th showed a profit of £1,717. 8s. 5d., which, with balance from previous year of £1,681. 19s. 7d., in all £3,399. 8s., was applied to writing off the debenture interest and other expenses prior to opening of cable for traffic.

NOTE ON THE UTILISATION OF WASTE WATER-POWER BY ELECTRICITY.*

BY ALBION T. SNELL.

On the Continent water-power is extensively used for driving electric plants, but in Great Britain, for a similar purpose, power is usually derived from the combustion of coal.

This difference in practice is partly the result, no doubt, of the relative supply of water-power in the neighbourhood of places where electric plants would prove commercially profitable; but it is also largely due to the relative cost of fuel. We do not possess abundant natural sources of water-power in or near our large manufacturing districts, and even if we did it is not probable that with coal at the average price of the last ten years, water-power would prove much cheaper when the capital invested, interest, and cost of maintenance of the electric plant were taken into consideration. But we may with reason pause to ask two questions: Will coal at such a price be always obtainable? And do we make the most of such water-power as we have and can profitably use? Let us look at the second question first. Liverpool is supplied with water from Lake Vyrnwy, in North Wales, the total difference of head being about 500ft. There must be a considerable quantity of power in the conduit. Is any of it utilised? And if not, does the reason lie in the fact that fuel at present is so cheap? Could the Manchester Water Works, which form a magnificent series of artificial lakes, be utilised to drive turbines and give electric energy for lighting the various towns in their vicinity? Again, the watershed behind Greenock has a fall of many hundred feet, and the water is only partly utilised to drive mills. These are only a few instances in which water-power might, perhaps, be advantageously used for driving turbine-dynamos. There are, of course, numerous mountain streams which could be dammed, and thus converted into reservoirs for feeding turbines.

England has been so prosperous in the past by reason of large supplies of coal, hitherto cheap and certain, that the consumers of power have scarcely realised the necessity of any change, and can with difficulty be brought even to contemplate the utilisation of waste water-power. On the Continent, however, coal is found in only a few districts, and fuel is generally dear in comparison with the prices current in Great Britain, and dearer still in relation to local wages and prices. Necessity has thus prepared Swiss, German, and Italian manufacturers, for a radical innovation, which gives them a cheaper power by utilising mountain streams. It is no mere figure of speech to say that natural obstacles in the way of trade competition have led to the development of this important branch of engineering on the Continent, while the very prosperity of Great Britain has tended to hinder progress in this direction. We may ask ourselves in all seriousness whether the present price of coal is likely to be maintained, and whether it would not be wise to make the most of such water power as we have by using it as an adjunct to, if not as a substitute for, coal. This is quite possible in many places, since power can be transmitted electrically at high pressure for distances of 20 miles or so with a loss not exceeding from 15 to 20 per cent.

The author then proceeds to describe several examples of the use of water-power on the Continent.

In England there are only a few installations which derive their power from water, such as the small central station for lighting Lynmouth and Lynton, and a few private installations. A scheme, on a large scale, for electrically lighting Worcester by means of power derived from the River Severn is in hand, and will, no doubt, lead to similar plants.

One of the most important instances of the application of water-power for electric power transmission in Great Britain at present is that at the Greenside Silver Lead Mines in Cumberland, which was designed by the writer about three years ago in conjunction with the mine manager, Mr. Borlase.

On the east slopes of Helvellyn lies a small natural lake called the Red Tarn, and on the north-east the impounded water of Keppel Cove. Between the two waters rises the hill of Catstycam, at the base of which the two overflows join, and near to which the Greenside Silver Lead Mining and Smelting Company have erected their turbine-dynamo station. The water is led from an elevation of 1,750ft. above sea level, and flows through an open watercourse 1¼ miles in length to a large reservoir, from which it is conveyed down the hill-side for a distance of 360 yards in 15in. cast-iron pipes. The fall at the station is equivalent to a vertical head of 400ft., and the effective horse-power is about 200.

The generating station contains one of Gilkes and Co.'s vortex turbines of 100 H.P., driving a four-pole compound dynamo made by the General Electric Power and Traction Company. The house is large enough to duplicate this plant when necessary, and pipes, watercourses, &c., are already laid for this purpose.

* Abstract of a Paper read before the British Association in Section G, Nottingham, September, 1893.

Digitized by Google

The electric current is conveyed by two bare copper conductors on poles for six furlongs, to where it enters the mine at an elevation of 1,850ft. above the sea level. The conductors from this point are insulated, and covered with lead. About three-quarters of a mile in the mine, or one and a-half miles from the dynamo, a 9-H.P. series motor is employed to wind ore from a set of sinkers. Further into the mine another quarter of a mile, and down 120 yards at the bottom level, is fixed another 9-H.P. motor, working a three-throw pump, forcing the water 360ft. in height.

About midway between these motors there is fixed a dynamotor, which reduces the pressure from 600 to 250 volts for working an electro-locomotive in the lowest day level of the mine, through which runs the water pumped from the 120-yards level and the whole of the water used by two hydraulic winding engines. Four horses formerly worked this level. The locomotive runs with 12 waggons, the total weight when loaded being 18 tons, and does the work of the four horses with the greatest ease. The conductors in the level are phosphor bronze wire, and the current is fed to the locomotive by four contact pulleys. The difficulties encountered in fixing this plant and wiring the level can only be appreciated by the practical man. All main stations in the mine are lighted by incandescent lamps in series of six.

The chief difficulty attending the use of water-power is the irregular and sometimes intermittent character of the supply, and hence it is necessary to exercise great care in judging the suitability of water for given work. This can be obviated to a large extent by building reservoirs and regulating the output according to the power required ; but when lighting forms an important part of the scheme, secondary batteries may be used most advantageously.

It will be gathered that the writer is fully aware the small water-power of Great Britain can never show results equivalent to those obtained on the Continent, yet there is undoubtedly much water-power wasted here that is capable of being profitably utilised. His object is simply to call attention to the improved means of utilising water-power by turbine-dynamos, and to suggest that prompt measures be taken to conserve as much power as possible by a proper attention to the building of dams and reservoirs wherever this may be feasible. And that such power should be used if convenient, to the exclusion of coal, and, if not so, as an auxiliary power, the steam plant being used as a stand-by as much as possible.

PARLIAMENTARY INTELLIGENCE.

HOUSE OF COMMONS : TUESDAY, SEPTEMBER 19TH.

On the resolution for the Post Office and Telegraph service, Mr. HENNIKER HEATON said that a grosser blunder had never been committed than for the Post Office to keep in their own hands the unproductive trunk telephone lines while they left the paying local lines in the hands of the private companies. He objected to the system of guarantees in connection with the establishment of local telegraph lines. The hon. gentleman then proceeded to comment on the rules laid down as to the charges for compound words. He submitted that the time had arrived when such anomalies should be put an end to. The public were so much irritated and worried by all the petty annoyances of the Telegraph Department that the Postmaster-General would suffer very little loss in revenue by allowing every compound word to be charged as one, and by putting an end to other petty grievances.

Sir A. ROLLIT spoke of the great interest which the municipalities had shown in the telephone, and considered that what was now proposed was not a restriction upon municipal action. It was not correct to say that the charge for the telephone was £20. When all the circumstances were taken into account he found that the average charge in London was £15. 0s. 7d., and in the provinces £8. 16s. 10d. He would not express an opinion as to whether a lower price would pay. His view was that the work should be done in the best form, in the belief that really good public service would in the end be most remunerative. The administration of the Department in this matter, both by the Postmaster-General and by his predecessor, had been such as to lead the National Telephone Company to desire nothing that was not fair and reasonable. Their desire was to consult the public interest, and he could assure the right hon. gentleman that in .the negotiations in regard to the agreement they would do their best with him to arrive at a right and fair conclusion.

Mr. A. C. MORTON said in his view the telephone companies wanted what was unfair and unreasonable. Their object was to secure by the aid of the Government a permanent monopoly. All he wished to say now was that the Act of last year was rushed through the House in a great hurry. He did not object to the Government purchasing the main lines, but he trusted that the Postmaster-General would do nothing to assist a monopoly. All he asked for was fair play.

Mr. A. MORLEY said the discussion had ranged over a variety of subjects, but he proposed to take the telephones first. He did not think he could fairly be asked to make a declaration of the policy of the Government on that question at the present moment. The recommendations of the joint committee which had been sitting would have to be carefully considered. He thought that the powers of the telephone companies to lay their wires ought to be subject to the sanction of the local authorities. The heads of agreement between the late Government and the National Telephone Company were drawn up and signed by his predecessor, and he thought a very considerable case would have to be made out to justify the House of Commons in departing from that agreement. The measure was the simple embodiment of a policy which was discussed more than once. With reference to the subject of competing telephone systems, he quite agreed that competition in the same area would destroy half the advantage of the invention. Parliament ought, therefore, to hesitate before sanctioning any arrangement under which there would be competing telephones in the same area. He now came to the schemes introduced under the late Government respecting Army Reserve men and telegraph messengers. The plan relating to the latter was that telegraph messengers who entered the service at the age of 13 or 14 should, upon reaching the age of 18, be turned out of the service unless they consented to serve with the colours for five years. If they consented to serve they were to have the right of re-entering the service as postmen at the end of five years. The reports which he received from postmasters of large towns were almost unanimous in declaring against this system. In these circumstances he would have incurred very considerable responsibility if he had allowed the new system to continue. The scheme which gave Army pensioners and Reserve men who wished to become postmen precedence over other applicants remained in full force. He thought the working of the rule would require watching, but at present he saw no reason to depart from it, and had no intention of doing so. With regard to telephone charges, comparison had been made between London and such towns as Stockholm and Melbourne. It would be fairer, he thought, that the comparison should be with towns like New York or Paris. In New York in business houses the charge was £50, in residences £37. In Boston the charges were £37 and £28, and in Philadelphia £25 and £21. In these three towns, therefore, which were smaller than London, the charges were considerably higher than here. It had been suggested that the charge for porterage in connection with telegrams might be done away with. In view of the fact that last year the loss in the Telegraph Department was very considerable, such a change could not be acceded to. In the course of the discussion some conundrums had been put to him respecting the charges for compound words in telegrams. He thought he might be excused if he did not answer them in detail. There were, doubtless, some anomalies, but it was difficult to lay down a general rule applicable to all cases. With regard to the extension of the postal telegraph service in the country, the last point to which he had to refer, he could quote some figures which would show that the department were doing their best to meet the increased demand. The number of additional telegraph offices opened in the year 1888-89 was 221 ; in 1889-90, 321 ; in 1890-91, 275 ; in 1891-92, 349 ; in 1892-93, 561 ; and this year, from April 1st to September 20th, 450. During the latter period of six months, therefore, a larger number of offices had been opened than in any full year preceding that period, except last year, and this was a proof that substantial progress was being made in this direction.

The resolution was then agreed to.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

The 1893 Edition of "'THE ELECTRICIAN' ELECTRICAL TRADES' DIRECTORY AND HANDBOOK" contains over 1,000 pages, several new and handy features having been added. Price 7s. 6d., post free 8s. 3d. ; abroad 8s. 10d. *Comparison with any similar electrical publication is specially invited.*

The 1894 Edition is in preparation, and will be published, as usual, in January. New names, alterations of addresses, &c., are received at any time, but the Directory blanks and circulars are not sent out until later in the year, in order that the most recent, and consequently the *correct*, addresses *only* shall appear in the book.

"DRUM ARMATURES AND COMMUTATORS."—This book, which is written by Mr. F. Marten Weymouth, and is the latest edition to *The Electrician* Series, is now ready, and will be sent direct by the publisher on receipt of the published price, 7s. 6d., or it may be obtained from any bookseller. A prospectus will be forwarded on application.

TENDERS INVITED.—The Corporation of Blackburn invite tenders for the supply and erection of machinery and plant for the electric lighting of the borough. There are seven separate contracts, as follows :—(1) Steam boilers and accessories ; (2) steam dynamos and accessories ; (3) travelling cranes ; (4) cables ; (5) conduits ; (6) accumulators ; (7) switchboards, &c. Plans may be seen, and full information obtained, on application to Mr. Thomas Barton, the electrical engineer, Ainsworth-street, Blackburn ; and tenders must reach Mr. Robert E. Fox, town clerk, not later than 12 noon on Friday, October 27th. Some further particulars appear in our advertisement columns.

——— Tenders are invited for the lighting by electricity of the Caledonia Foundry and Engine Works, Brasenose-road, Liverpool. All information can be obtained from the proprietors.

Digitized by Google

TENDERS INVITED.—The Directors of the Gas Light and Coke Company announce in our advertisement columns that they are prepared to receive offers for the purchase of the Company's make of retort carbon at their several stations, for one year from the 30th inst. Offers should be sent in before October 3rd. Further particulars may be obtained from the chief office of the Company, Horseferry-road, Westminster, S.W.

——— The Directors of the Great Western Railway invite tenders for the supply, from November 1st next to October 31, 1894, of various stores, amongst which are telegraph instruments, telegraph apparatus, telegraph iron work, &c., telegraph drysalteries, carbons for electric light, telegraph poles, &c. These tenders must be sent in on or before Monday, October 2nd.

TENDERS ACCEPTED.—The Ealing Local Board have accepted the tender of the Callender's Bitumen, Telegraph and Waterproof Company (Limited) for the supply of the mains for the electric light installation, and that of Messrs. Paterson and Cooper for wiring the public buildings. The following are lists of the tenders sent in :—

For Mains.

Fowler-Waring Cables Company	£6.199	2	10
Callender's Bitumen, &c., Company (accepted)	6,291	8	8
Siemens Brothers and Co.	6,863	0	0
British Insulated Wire Company	7,570	7	8
Reid Brothers	8,190	19	0
Johnson and Phillips	8,336	6	0
W. T. Henley's Telegraph Works Company	8,924	11	10

For Wiring the Public Buildings.

Binko and Co.	684	18	6
Brown and Co.	700	0	0
Spagnoletti and Crookes	793	0	0
Paterson and Cooper (accepted)	795	16	2
Tayler-Smith Electric Company	842	0	0
Emanuel (A.) and Sons	853	15	0
Lund Brothers and Co.	871	4	6
Howard and Co.	875	18	0
Ronald A. Scott	903	0	0
Brush Electrical Engineering Company	920	11	9
Rashleigh Phipps and Co.	990	0	0
Rawlings Brothers	1,020	7	0
Johnson and Phillips	1,099	9	0
British Electric Light Company	1,119	0	0
Nicholson and Tyler	1,125	10	4
Thomas Digby	1,130	0	0
Julius Sax and Co.	1,149	18	9
Baily and Grundy	1,188	0	0
MacLellan and Co.	1,249	12	3
Roger Dawson	1,252	0	0
Crompton and Co.	1,259	0	0
Strode and Co.	1,277	15	3
S. Cutler and Sons	1,362	0	0
R. Verity and Sons	1,376	6	6
W. Mackie	1,611	5	3
Tickner and Partington	2,187	5	6

PLANT FOR SALE.—Messrs. Sharp and Kent announce in our advertisement columns that they have for sale a complete electric light generating plant, suitable for 300 16-c.p. lamps.

APPOINTMENT VACANT.—It will be seen by our advertisement columns that the Southampton Harbour Board require the services of an electrical mechanic to attend to the electric cranes and the electric lighting. Particulars can be obtained from Mr. A. H. Skelton, the clerk, up till Saturday, the 30th inst.

PERSONAL.—Mr. Walter James Smith, lately assistant in the Liverpool Corporation's electric laboratory, has been appointed electrical inspector for their district by the Toxteth Park Local Board.

LIQUIDATION.—A meeting of the National Telegraph Works Company (Limited) is to be held at Mr. James Rhodes's, 34, Waterloo-street, Birmingham, on the 27th prox., at 4 p.m., to receive an account of the winding-up.

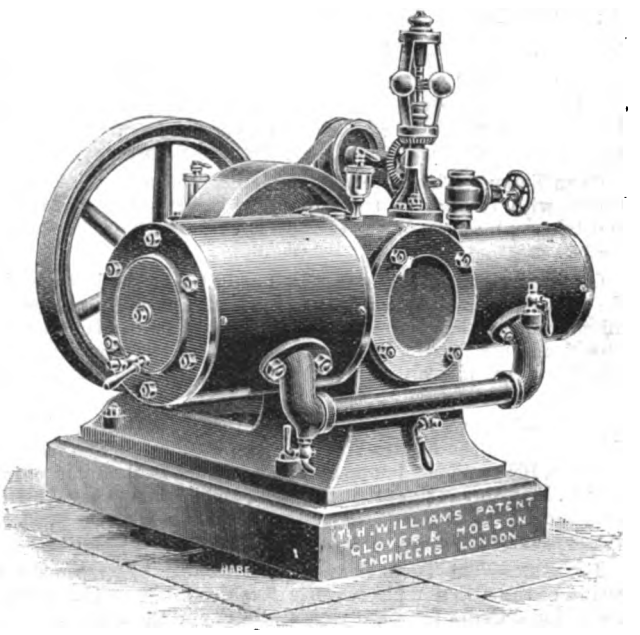
MESSRS. DRAKE AND GORHAM.—This firm carried out the temporary electric light installation in connection with the recent Primrose League demonstration at Haddon Hall, the seat of the Duke of Rutland. Four Crompton-Pochin arc lamps were arranged on the towers, affording light to a considerable distance in the extensive grounds.

ELECTRIC LIGHT LETTERS FOR ADVERTISERS.—These electric letters are formed of bright plated metal backings, of hollow section. Into these backings, glass tubes of uniform diameter and various lengths, enclosing a filament, are fitted. The appearance of the electric light advertisements or signs formed of these letters is of an unusual and striking character. They are most especially suited for theatres, railway stations, exhibitions, restaurants, hotels, shops, advertisements in tunnels, underground railways, and every other place where an ordinary advertisement would be utterly useless. These electric light letters mounted on a skeleton frame, and suspended within the window, afford a brilliant advertisement and a brilliant light, thus rendering any other form of window lighting wholly unnecessary. The Electrical Advertising Syndicate (Limited) are the proprietors of the invention, and are already erecting these signs in London. The letters in question have been designed by Mr. Réné Upward, who is consulting engineer to the Syndicate. The letters and signs are manufactured complete in every respect, and mounted ready for erection, without added resistances, by the Edison and Swan United Electric Light Company (Limited) at their Ponders End works.

MACHINE TOOLS.—Messrs. Lotz, Abbott and Co., of High Holborn, inform us that they have been appointed sole selling agents for Great Britain, the Colonies, and also for the United States of America, for the sale of Pittler's Universal Lathe.

WRIGHT'S PATENT HEATER AND CONDENSER COMPANY.—This Company sends us an illustrated circular and price list of their feedwater heaters, condensers, and steam engines. They claim several advantages for their compound cylinder release engines.

WILLIAMS' HIGH-SPEED VALVELESS ENGINE.—It is claimed that this engine, which is being shown at the Laundry Exhibition, Islington, presents some remarkable features in economy, simplicity, and silent running. It has only three main working parts,



viz., the piston, crank-shaft with a curious oblique ball-and-socket crank, and crank-pin bearing; it has no valves, piston, or connecting rods, nor are the pistons packed. The pistons act as steam valves, and can be arranged to cut off steam at any part of the stroke. The engine, which is now being exhibited, gives 16 I.H.P. at 420 revolutions per minute.

ALTRINCHAM.—The contractors have commenced to lay mains for the proposed electric lighting of the town. The installation scheme includes the erection of plant at Broadheath, and the extension of the system to Rowdon and parts of Dunham Massey. The Manchester Edison-Swan Company has the contract.

AYR.—At the last meeting of the Town Council, Mr. Morton asked what was being done in connection with the electric light. He thought the policy of the Council was a dog-in-the-manger one; they were not doing anything themselves, nor allowing anyone else to do anything. Other members defended the delay, and it was pointed out that if the inhabitants said they would like the electric light the Council were prepared to take action immediately, but until they did so it would not be wise to move in the matter. At the same time, the idea of letting the Provisional Order pass out of the hands of the Council was deprecated.

BATH.—Complaints having been made as to the times at which the electric light is switched on and off, the surveyor has drawn up a table giving the exact time every day in the year at which the light should make its appearance and be extinguished. The table was explained at the last meeting of the Town Council, and after some discussion it was decided to turn the light on and off according to the table for three months.

BECKENHAM.—At the last meeting of the Local Board a letter was read from the Secretary of the Crystal Palace District Electric Supply Company (Limited), stating that the Company's mains had been laid in several thoroughfares within the Board's district, and

Digitized by Google

asking whether the Board were prepared to entertain proposals for lighting these localities by electricity.

BRECHIN.—The Police Commission last week passed a resolution empowering the Watching and Lighting Committee to consider the question of the lighting of the new municipal buildings by electricity, and to report on the probable cost.

CAMBORNE.—The premises of Messrs. Holman Bros., iron-founders, are now lighted by electricity. Messrs. Veale and Co. (Limited) have laid down an installation consisting of 46 incandescent lamps and several arc lamps, ranging from 2,000 to 500 c.p. the current being generated by a Crompton dynamo. This is the first electric light installation in Camborne, and, with the exception of the Dolcoath mine, the first in the neighbourhood.

CAMBRIDGE.—The Guildhall and Building Committee of the Town Council reported at the last meeting of the Council that, in reply to their request for estimates for the installation of the electric light in a portion of the Guildhall, two estimates had been received from local firms, and they recommended the Council to accept that of Messrs. Medhurst (now Messrs. Russell and Co.) at £37. 5s., subject to a slight alteration in the lamps, which would entail an additional cost not exceeding £5. The adoption of the Committee's report having been proposed, Mr. F. Morley inquired the name of the second firm tendering and the price they tendered at ; but the Deputy-Mayor said that he did not think it was necessary to state the name of the firm, but the price asked was more than double. Mr. Morley said that if a good firm could not do work of this kind for less than £70 he did not think another firm could do it properly for £37. Mr. Bell having explained that the difference in the cost was owing to simpler arrangements being employed which gave the same results, the report was adopted.

CAPE TOWN.—The Government are negotiating with the Harbour Board with respect to the supply by the Board to the new Post and telegraph offices of the electric light from their station in the docks.

CHESTERFIELD.—The Town Clerk reported at the last meeting of the Town Council that, although he had sent 261 circulars to the inhabitants of the compulsory area referred to in Mr. Shoolbred's report, inviting particulars of the anticipated requirements of electrical energy, if such were provided by the Council for private lighting, only thirteen replies had been received.

CORK.—The new offices of the Lady's Well Brewery have been fitted up with the electric light by Mr. Percival. The installation includes 104 pendant lamps of 150 c.p. each in the main office, six 32-c.p. lamps over the principal desk, and 18 lamps are distributed over the ties of the roof, the general effect being very good. Mr. Percival has also fitted up telephones throughout the offices.

FALKIRK.—The Town Council have decided to oppose the application of the Caledonian Electric Supply Company (Limited) for a Provisional Order for supplying electricity in the Burgh.

GREAT YARMOUTH.—The Town Clerk stated, at the last meeting of the Town Council, that the Local Government Board, prior to sanctioning the loan required for the purpose of electric lighting, insisted that the site upon which it was proposed to erect the building should be vested in the Urban Authority. The Finance Committee, therefore, recommended the Council to grant to the Urban Authority, for the purpose of an electric light station, a piece of land on the east side of the Southgates-road. The recommendation was adopted.

HOVE.—The Local Government Board have given their sanction to the Commissioners borrowing £1,400 for the purpose of lighting the Town Hall by electricity, stipulating that the loan be repaid within a period of 10 years. It was moved that the question be dropped, but on a division it was lost. The appointment by the Electric Light Committee of Mr. E. F. J. Hewlett as electrical engineering assistant was confirmed by the Committee.

HUDDERSFIELD.—The Corporation's electric lighting scheme originally provided for the supply of current for the purpose of illumination to the central business part of the town ; but in consequence of numerous demands for the light for residences in the Edgerton district, mains for its supply are being laid. When completed the extension will cover a lineal measurement of about two miles, a considerable number of the large residential establishments receiving installation. The Technical School and the Borough Club are amongst the buildings in Bradford lately fitted up with the electric light.

LEWES.—The Works Committee of the Town Council have instructed the Town Clerk to make inquiries as to the cost of obtaining a Provisional Order for lighting the town by electricity.

MAIDSTONE.—Mr. Barker asked, at the last meeting of the Local Board, what had become of the electric light question ; it seemed to him to have dropped. The Town Clerk replied that a meeting of the Committee would be held very shortly ; it had been delayed owing to the absence of several members.

NEWPORT (MON.).—The Electric Lighting Committee have recommended the Town Council to appoint Mr. Robert Hammond as consulting electrical engineer, and that he be paid a commission of £5 per cent. on the cost of the installation (exclusive of land), to cover all the travelling and out-of-pocket expenses, and the service of a resident engineer to act as clerk of the works.

NEWTOWN (SHROPSHIRE).—A discussion arose at the last meeting of the Local Board on the question of lighting the town, and Capt. Pryce-Jones said a report had been received from some electricians on the subject of lighting the town by electricity, and, although they saw there would be many advantages, it could not be adopted at present, because it was probable that great strides would be made in the science, and electric light would most likely become much cheaper. After some discussion the subject dropped.

NORMANBY.—At the last meeting of the Local Board a member referred to the excessive cost of gas lighting, and moved that the Board should take into consideration the question of electric lighting. This was agreed to, a sub-committee being appointed to go into the matter.

PAIGNTON.—At the last meeting of the Local Board, a letter was read from Messrs. S. D. Williams and Co., of Newport (Mon.), asking if the Local Board were in a position to consider the question of lighting the district by electricity. If so, Messrs. Williams and Co. were prepared, in return for the concession, to provide and work the necessary plant. A letter was also read from the general manager of Messrs. Woodhouse and Rawson United (Limited), of the same tenor, and asking also if the Board were prepared to entertain a scheme for running electric launches for ferry-boats to and from Torquay. After some discussion, the letters were referred to a committee.

RYDE.—A letter was read at the last meeting of the Town Council from Mr. C. B. S. Lay, of the National Telephone Company, stating that a public meeting would shortly be held with a view of establishing a telephonic exchange between the various towns in the Isle of Wight.

SHOREDITCH.—The Electric Lighting Committee of the Vestry reported last Tuesday that they had considered the reference back to them of their report on the Pitfield-street site, with instructions to make a further financial statement and report. So far as the electric lighting scheme is concerned, the committee think that the report of Mr. Manville contains the fullest financial information that can be afforded until a site has been actually acquired. With regard, however, to the dust utilisation part of the scheme, and the amount of heat which would be available for baths and washhouses and motive power, they thought it would be advisable and very useful in a scheme of this magnitude to obtain a financial report from Messrs. Manlove, Alliott and Co. (Limited). The committee have accordingly instructed this Company to report what results they could guarantee with regard to the cost of burning 20,000 tons of dust per annum, and the amount of heat which would be available for baths and washhouses and electric lighting purposes, and the capital cost of maintenance. The charge for the report is not to exceed £10. 10s.

TAUNTON.—The Corporation announce that they will be prepared to supply electricity from their central station from October 1st.

WARMINSTER.—It had been suggested that the electric light should be supplied at the fountain ; but at the last meeting of the Local Board Mr. Chambers said it appeared that the probability of the fountain being so lighted was rather distant, and, as the winter was approaching, he suggested that a Sugg lamp should be placed there. Another member, however, said he had hopes the electric light matter would be arranged very shortly ; and it was agreed to leave the question in abeyance.

WESTON-SUPER-MARE.—At the last meeting of the Town Commissioners the Inspection Committee reported that they had been waited upon by a representative of the firm of Messrs. John Fowler and Co., Leeds (Limited), who said that his firm would be willing to prepare and submit a scheme and estimate for fitting up an electric lighting station and laying down plant within the compulsory area. The Committee, however, explained that, as the Board were in negotiation with the Brush Electrical Engineering Company, they could not give his firm any instructions at present.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announce the payment on October 13th next of interest of 3s. per share (less income-tax), being at the rate of 6 per cent. per annum, on the Preference shares of the Company for the quarter ending September 30th, and the usual interim dividend of 2s. 6d. per share on the Ordinary shares (free of income-tax) in respect of profits for the quarter ended June 30th. The register of transfers will be closed from October 6th to 13th, both days inclusive.

NEW COMPANIES, STATUTORY RETURNS, &c.

[*In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1893, pages 320-348, *&c., &c.*]

CALVERT AND CO. (LIMITED).—This Company was registered on September 18th, with a capital of £2,000, in £1 shares, to acquire, take over as a going concern, and carry on the mechanical, electrical, and general engineering business carried on under the trade name of "Calvert and Co.," at Wandsworth, S.W. The first Directors are F. G. Hughes, J. R. Thame, and F. H. E. Shipton.

ELECTRO-PROTECTOR SYNDICATE (LIMITED).—This Company was registered on September 16th, with a capital of £10,000, in £1 shares, to acquire, develop, and turn to account certain patents, patent rights, inventions, licences, &c., particulars of which are not given, with a view to adopt and carry into effect an agreement made between Robert Jewell and Charles O. Greenwell (for the Company), and to carry on the business of electricians, mechanical and electrical engineers, suppliers of electricity, and manufacturers of and dealers in mechanical and electrical apparatus for registering the receipts of moneys. The subscribers (with one share each) are:—C. O. Greenwell, 63B, Elizabeth-street, Eaton-square, S.W.; E. G. Saunders, Nithwater House, Barnes, S.W.; C. E. Masterman, 6, Thorny Hedge-road, Gunnersbury; A. H. Portch, 38, Scylla-road, Peckham Rye, S.E.; T. E. Smith, 13, Clifton-crescent, Sutton; A. W. Letts, 59, Broad-street-avenue, E.C.; and R. R. Garratt, 59, Broad-street-avenue, E.C. The first Directors are Thomas Beard, A. H. Macnaughten, Edward S. Claremont, and H. E. Saunders.

JEREMIAH COWDY AND CO. (LIMITED).—This Company was registered on September 13th, with a capital of £10,000, in £1 shares, to purchase and carry on the business of iron and steel merchants, lamp manufacturers, iron and brass founders, wire drawers, &c., carried on by Jeremiah Cowdy and Co.

MARCHANT, YOUNG AND CO. (LIMITED).—This Company was registered on September 14th, with a capital of £4,000, in £1 shares, to carry on the business of electrical and mechanical engineers, and any business connected therewith. The subscribers (with one share each) are:—S. F. St. Steadman, 23, Old Broad-street, E.C.; J. E. Marchant, 166, Clerkenwell-road, E.C.; C. T. Young, 19, Woburn-place, Russell-square, W.C.; H. C. Campion, 23, Old Broad-street, E.C.; G. Groves, 48, Sarsfield-road, Balham; F. H. Robinson, 12, Percy-road, North Finchley; G. C. Hay, 126, Chesterton-road, Kensington. The first Directors are:—Bernard J. Young, John E. Marchant, and Charles T. Young. Registered with the Memorandum and Articles of Association of this Company was an agreement, dated September 13, 1893, made between John E. Marchant and Charles T. Young (called the vendors), and Cooper Corbidge (acting on behalf of the Company), and providing for the sale to the Company of the business of electrical and mechanical engineers carried on by the vendors at 166, Clerkenwell-road, London, for £1,780, payable by the allotment as fully paid of 624 shares to John E. Marchant, and of 1,156 shares to Charles T. Young. The vendors are appointed Managing Directors at a salary of at least £3 each per week.

ROTHERHAM FORGE AND ROLLING MILLS COMPANY (LIMITED).—This Company was registered on September 13th with a capital of £25,000, in £20 shares, to acquire, develop, and turn to account the business of manufacturers of steel and iron forgings and rollers of steel and iron, carried on under the same name.

SHILLINGFORD WORKS COMPANY (LIMITED).—This Company was registered on September 14th with a capital of £10,000, in £1 shares, to acquire, by purchase or otherwise, and carry on the business of mechanical and electrical engineers, millwrights, toolmakers, machinists, brass and iron founders, boiler makers, electricians, &c., carried on by the Shillingford Works Company.

WOLVERTON AND STONY STRATFORD DISTRICT NEW TRAMWAY COMPANY (LIMITED).—This Company was registered on September 15th with a capital of £5,000, in £100 shares, to acquire a tramway at present carried on at Wolverton and Stony Stratford, Bucks., and to work the same with steam, electrical, mechanical, animal, or other power.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY (LIMITED).—When the return of this Company was filed on August 28th, the whole nominal capital of £600,000, in shares of £10 each, had been taken up and paid for in full.

ECUADOR TELEPHONE COMPANY (LIMITED).—The annual return of this Company, made up to August 10, 1893, has been filed; 5,000 shares out of a nominal capital of £100,000, in £5 shares, have been subscribed for and allotted, and upon these shares the full amount has been called, and all calls have since been paid.

EDISON AND SWAN UNITED ELECTRIC LIGHT COMPANY (LIMITED).—The annual return of this Company made up to August 11th, has been filed. The nominal capital is £1,000,000, divided into 150,000 "A," and 50,000 "B" shares, of £5 each; 106,400 "A" and 23,564 "B" shares have been taken up; 82,261 "A" shares have been issued, with £3 per share considered as paid, and 17,139 "A" and 23,564 "B" shares have been issued as fully paid, representing a total amount of £426,667. 10s. Upon the 89,261 £3 paid "A" shares a call of 10s. per share has been made, resulting in the payment of £44,630. 10s., this being the working capital.

ELECTRIC AND GENERAL INVESTMENT COMPANY (LIMITED).—No changes have been made in the number of shares taken up in this concern since the last return was filed, 20,000 Ordinary and 100 Founders' shares being the number allotted. £1 per share has been called on the former and the full amount on the latter, the whole totalling £20,500.

ELECTRICAL POWER STORAGE COMPANY (LIMITED).—The annual return of this Company, made up to August 10th, shows that 70 Founders' and 18,657 Ordinary shares, each of the value of £5, have been taken up; 15,120 of the Ordinary shares were issued as fully paid, and a call of £3 per share has been made on the remaining 3,537 shares, while the full amount has been called on the 70 Founders' shares. The calls paid amount to £9,221. 18s. 9d., while £1,369. 1s. 3d. is still in arrears. In consequence of non-payment of calls, the holders of 200 Ordinary shares have forfeited the £2 per share previously paid on them.

EXCHANGE TELEGRAPH COMPANY (LIMITED).—The return of this Company for 1893, made up to August 16th, has been filed. The nominal capital is £246,250, divided into 8,125 "A" and 16,500 "B" shares of £10 each. All the "A" and 16,200 "B" shares have been subscribed for, the "B" shares being considered as fully paid. 2,125 "A" shares were issued, with £8 per share considered as paid. On these same shares a call of £1 per share has been made, and on the 6,000 "A" shares remaining £9 per share has been called, resulting in the payment of £56,023, leaving £102 in arrears.

MANCHESTER EDISON-SWAN COMPANY (LIMITED).—The annual return of this Company, made up to July 28th, has been filed. The nominal capital is £550,000, divided into 50,000 "A" shares of £9 each, and 10,000 "B" shares of £10 each. 20,000 "A" and 10,000 "B" have been taken up. £1 per share on the former has been called, while upon the latter the full amount has been called, the payments realising a total of £120,000.

MUNICIPAL ELECTRIC LIGHT AND POWER CORPORATION (LIMITED). The annual return of this Company for 1892, made up to December 31st, was recently filed. The nominal capital is £25,000, divided into 2,490 Ordinary shares of £10 each and 100 Founders' shares of £1 each. Thirty-seven Ordinary and 30 Founders' shares have been taken up, the full amount called, and £400 paid. The 1893 return, made up to July 13th, and filed with the foregoing, shows that no changes have been made.

CITY NOTES, &c.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended September 17th were £756, as against £744 for the corresponding period of last year, being an increase of £12. The total receipts for the half-year amount to £8,880, against £8,440 in the corresponding period of 1892, being an increase of £440.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY (LIMITED).—The Directors of this Company on Wednesday declared an interim dividend, for the quarter ended June 30th last, of 2s. 6d. per share, free of income-tax, payable on the 14th prox. The Share Register will be closed from the 6th to the 13th prox., both days inclusive.

GLOBE TELEGRAPH AND TRUST COMPANY (LIMITED).—The Directors have declared an interim dividend of 3s. per share on the Preference and 1s. 6d. per share on the Ordinary capital.

LIVERPOOL OVERHEAD RAILWAY COMPANY.—A second call of £2 per share on the Preference shares has been made, and is payable at the Bank of Liverpool (Limited) Water-street, Liverpool, on Monday, October 9th.

ROCKHAMPTON (QUEENSLAND) GAS AND COKE COMPANY (LIMITED). The report of the Directors for the half-year ended June 30, 1893, presented at the meeting held on August 11th contained the following:—Taking everything into consideration the Directors have reason to congratulate the shareholders upon the satisfactory results of the past half-year. With the gloomy and unprecedented state of financial matters characterising the past few months, and the consequent depression and insecurity in commercial affairs generally, the Directors had somewhat feared the Company would have felt the effects very much more seriously than it has done. The gas operations show a profit of £1,940. 14s. 9d. The electric light operations show an actual loss of £115. 15s. 5d., to which is added £289. 13s. 7d. interest upon the capital involved in the electric light plant and buildings, &c., making a debit balance in all of £414. 9s. The net profit for the whole of the Company's business is therefore £1,526. 5s. 9d. A great improvement appears in the electric light revenue as compared with that of the preceding half-year, while the working expenses are much reduced. The number of customers for the light is increasing, and public lighting with high-power arc lamps will be inaugurated on the Fitzroy Bridge in the course of a few months. In view of the large sum vested in the gas interests the Directors have thought it inadvisable to push the electric lighting operations, but have preferred to allow this portion of the Company's business to expand on its own merits and in response only to unsolicited applications for the light. The Directors anticipate being able to report an actual profit upon the electrical business at the next meeting of shareholders. The Directors recommend the payment of a dividend at the rate of 10 per cent. per annum, amounting to £1,724. 18s. 2d., which will necessitate the appropriation of £200 of the reserve fund for equalisation of dividends.

Digitized by Google

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended September 15, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £1,220.

WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED.)—The receipts of this Company for the two weeks ended September 15th were £1,840, as compared with £2,163 for the corresponding period of last year. The May receipts, estimated at £7,655, realised £7,608.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 802.—Vol. XXXI. FRIDAY, SEPTEMBER 29, 1893. PRICE FOURPENCE.
Annual Subscription (U.K.), 19/6

NOTES.

The experiments on the transmission of signals, not through space but through sea-water, by Mr. Willoughby S. Smith in our present issue are certainly less magnificent than those of Mr. Preece, but owing to the uncertainty as to the nature of the latter no useful comparison can be made between them. The equipotential curves, shown in the present communication, would be precisely the same in an ocean of mercury. The fact that the currents which Mr. Willoughby S. Smith has employed may be detected at a greater distance, in a bad conductor like the earth than in a good conductor like sea-water, can be explained in quite a different fashion from that adopted by Mr. Preece; for in all his experiments the receiving instrument acted like a voltmeter; and as, for a given total leakage current through the earth, the voltages must be smaller in proportion to the conductivity of the soil, it follows that with bad conductors the potentials will be high, and the earth currents can be detected at greater distances than with good ones. The experiments by the late Mr. Willoughby Smith were described in *The Electrician*, Vol. XXI., pp. 492 and 832.

"I think you are rather down on the small wiring firms in last week's leader," writes a correspondent. "It is true these people require a rap on the knuckles occasionally, but these 'electrical micro-organisms' have a function in connection with the supply from central stations in getting business and lights. I wish we could set a few more of them to work." It was with no intention whatever to rap them on the knuckles that we called attention to these useful microbes. We made a passing reference to the rawness of some of them. "Everything must have a beginning," may be pleaded. True; every dentist must draw his first tooth from somebody's head, but the public have no means of distinguishing between these beginners and experienced firms, many of which make not only business but an art of wiring, especially in elaborate and well-decorated houses; such work demanding a great deal of ingenuity, principally because it is not carried out in conjunction with the architect. The high-class instruction in electrical engineering given by the technical colleges is useless here, and is thus often wasted. We would much rather see young plumbers, house-carpenters, and gas fitters receiving "technological" instruction on practical electric wiring, say, at Finsbury, at the evening classes, and thus enable tradesman to employ intelligent and competent hands, than see young men who have had a technical and perhaps a scientific training drifting, or pressed by over-crowding, into this useful trade. But we repeat it was hardly for this work that parents "put" their sons "into electric light."

The great expenditure of electrical energy in starting electric locomotives has been frequently alluded to in these columns. Part of this expenditure goes to the work of acceleration in starting the car or train, but a great deal of it is wasted. Force is wanted more than work, especially for the first few seconds, but force cannot be obtained without work; that is to say, the driver cannot get amperes without taking the volts. Mr. W. W. Beaumont's variable gear, which was described in *The Electrician*, Vol. XXX., p. 564, was designed to lessen their loss. At the British Association, in Section G, Mr. Beaumont described two modified arrangements of this gear. In one of these he has been able to abandon the electric clutch, very properly preferring a mechanical arrangement where possible. He has also avoided the use of wheels running idle at high speeds. A second design has been made for tramcars on which single reduction gear is employed. It seems a pity to use any permanent gear when Mr. Beaumont's ingenious mechanism itself provides so complete a range of gear. Gearless locomotives are in regular use in America, but the cars are run at higher speeds than would be tolerated in this country, and first cost seems to be no object. Two motors should be used if only to provide for the possible breakdown of one; and having two, Dr. J. Hopkinson's method of coupling them in series or in parallel provides in effect another range of gearing for hill climbing. We look forward, therefore, to the use of Mr. Beaumont's gear on otherwise gearless tramcars as well as on electric railways.

The pure waste of current in starting a motor, apart from the work of acceleration when it has to start with a load, is even greater with alternate currents than with continuous. Some so-called self-starting motors are almost useless on this account. We understand that the Oerlikon Company, who have brought multiphase motors to a practical form, no longer recommend the use of this system for supplying power and light from the same mains. They have found it impossible to adjust the load on the different circuits so as to avoid large variations of voltage at the starting of motors of even small power. In the recent trials by M. Turettini at the Geneva central station of a new 10 H.P.

Digitized by Google

motor, the current at starting was 250 amperes at 110 volts, or equivalent, as far as the mains are concerned, to a draught of 37 H.P., for a very appreciable period. Judging from the state of the alternate-current motor business in this country it would seem that any further contribution to the mathematical discussion and theoretical design of such machines is for the present superfluous. But for simple cases of transmission of power, as well, perhaps, under certain conditions which are not yet very clear, of distribution of power, such motors are likely to be used elsewhere, and we therefore have no hesitation in printing an article from Herr EMIL KOLBEN, who during the past two years as chief engineer to the Oerlikon Company has had exceptional opportunities for designing and testing a large number of alternate-current motors. The article contains a great number of formulæ, some of which are rather complicated, but it is, nevertheless, a useful one, and keeps well to the point. There is no attempt to lengthen the argument by needless allusion to theoretical points, and some of the formulæ given are empirical, and contain numerical constants founded on experience alone.

IN the course of the discussion which followed the description of a ballistic galvanometer by Dr. OLIVER LODGE, at the British Association, Prof. FITZGERALD made a proposal of great interest in connection with the observation of very small motions of rotation. We have asked Prof. FITZGERALD to explain his idea more fully. He tells us that it is nothing more than a suggestion, but we are glad to be able to give it in his own words in another column. It seems probable that the displacement of interference bands, which has been employed by MICHELSON for measuring double star distances and the satellites of Jupiter, may be of great use in physical measurements on what Dr. STONEY has called the borderland of the visible. An interference method for measuring the diameter of small wires ought not to be difficult to contrive or to use.

THE interest which was evoked during the last session of the Institution of Electrical Engineers, by the Paper by Mr. W. B. SAYERS on his ingenious mode of producing an exciting field in dynamos without the use of field-magnet coils, was renewed at the British Association meeting at Nottingham. As this town is within half-an-hour's journey of Derby, at the Midland railway station of which town these novel dynamos are now in use, we have no doubt that many electrical B.A.'s made a pilgrimage for the purpose of examining them. We found these dynamos in one corner of the remarkably trim and pretty generating station belonging to the Midland Railway Company, where they are employed as regulators or balancing machines on the three-wire mains for lighting the railway station, offices, and yard. As it was high noon when we paid our visit, there was no difficulty in detaching the regulators from the circuit and subjecting them to a full-load test. It has been predicted by theorists that the notched method of winding the armature must give rise to considerable heating. We found, however, that after a considerable run with a current in the armature much above the normal, the armature was not warmed perceptibly; it was as cool as the bed-plate, and certainly cooler than the commutator or the bearings. The whole machine, in the case of each regulator, ran smoothly, and with little heating. The regulators are driven by motors on the lighting circuit.

IT is without surprise that we note that Dr. OETTEL'S claim to originality in the observation of the behaviour of an unconnected plate hanging between anode and cathode in an electrolytic cell, which we have already gently ridiculed, has been denied in all seriousness in the correspondence columns of the journal—the *Chemiker Zeitung*—in which his communication first appeared. The *advocatus diaboli* in this case is Herr A. VOIGT, and he quotes English authorities (GUTHRIE and BOYS, *Phil. Mag.*, 65, 4, 328, 1880) in support of his contention. Like ourselves, however, he pays a tribute to Dr. OETTEL'S careful presentation of the quantitative side of a well-known phenomenon.

THE note in our last issue on the use of high-frequency discharges by M. D'ARSONVAL and by Prof. D'ODIARDI has called forth a letter from the latter. The communication deals, however, with the medical side of the subject, and must therefore be excluded from our columns. We reminded our readers a twelvemonth ago that English medical men observe a self-imposed rule which forbids communication on medical subjects to non-medical journals and scientific societies, and we intend to respect this convention.

THE series of three articles by Prof. POYNTING, which we commence this week, were written in response to our request for a review of Dr. OLIVER LODGE'S second edition of his "Modern Views." In these articles Prof. POYNTING makes a critical examination of the hypothesis, or rather the hypotheses, of Dr. LODGE, but in perfectly plain language, and without going into any mathematics. It seems to us to be a matter of great importance that clear distinctions should be made between analogies, working hypotheses, and theories. In Dr. LODGE'S book it is difficult to find such distinctions, and the reader who is delighted with simple mechanical arrangements of cog-wheels, as analogies, is left in doubt as to whether any suggestion is intended that an atomic ether actually works in this way.

Cable Interruption:

	Date of Interruption.
Pernambuco-Ceara	September 1st.

Electric Traction on the Canadian Pacific Railway.—It is stated, says *Industries and Iron*, that the Canadian Pacific Railway Company will adopt electricity for drawing trains up a cañon known as Kicking Horse Pass.

Electric Traction in Madrid.—We understand that the Allgemeine Electricitäts Gesellschaft is connected with the new company which has been formed in Berlin, with a capital of 7,500,000fr., for the purpose of introducing electric traction into the tramway systems of Madrid.

Electrical Communication with Lighthouses and Lightships. A Bill has been introduced into the United States Senate directing that experiments shall be made to determine the most

Digitized by Google

effective means of establishing and maintaining communication by telephone or other electrical apparatus between lightships and outlying lighthouses and the shore.

Search-Lights and Night Attacks.—An interesting and instructive night attack was made at Portsmouth last week. The primary object was to determine how far the electric lights of shore defences are efficient for lighting up vessels attempting to approach the harbour. As far as observation went, the electric lights appeared too feeble for the purpose contemplated.

Switzerland.—Two new lines of electric railways, recently constructed by the Compagnie de l'Industrie Électrique, of Geneva, are shortly to be opened to the public. The one of these is an extension from Veyrier to Monnetier, of the Salève mountain railway described in *The Electrician*, Vol. XXXI., p. 494. The other extends from Orbe to Chavornay, and is constructed to take ordinary goods trucks.

Popular Lectures.—At the Royal Victoria Hall, Waterloo Bridge-road, during October, Dr. Halliburton will lecture on "Electrical Fishes," and Prof. Reinold on "The Compass in Iron Ships." At the great Assembly Hall, Mile End Road six Gilchrist lectures will be given on alternate Thursdays, beginning September 28th. Prof. J. A. Fleming will lecture on "Magneto and Electric Currents" on October 26th.

Electric Tramway Return Leads.—The latest idea in electric traction is the method proposed by the late Lord Alfred Spencer Churchill. Instead of an uninsulated return, he proposed to employ a buried insulated conductor, and at every 20ft. or so to erect a special contact piece above the roadway. On the car there is to be a brush so long that it will always touch one of these contacts, and thus always be in communication with the main conductor.

Telephonic Communication on the East Coast.—The Post Office authorities have decided to lay a cable from the Gunfleet Lighthouse to the Old Gapway, at Frinton, near Walton-on-the-Naze, as the first portion of the telephonic communication between the various lighthouses and vessels and the coastguard stations at Harwich, Walton, and Clacton, all three of which will be connected by a land wire. The operation of laying the cable is now in progress.

Lausanne.—We are informed that very extensive system of electric power distribution has been submitted to the Town Council of Lausanne. It is proposed at first to take about 1,200 H.P. from the River la Grand Eau, near Aigle, at 40 kilometres from Lausanne. This would be used for supplying about 5,000 16-c.p. glowlamps during the hours of darkness, and in daylight the power would serve to pump water from the lake to supply the town. The surplus energy would be devoted to driving motors for tramcars, and in shops and factories.

Telephoning in the Navy.—Telephonic communication has been established between the "Lion," training ship, and the Royal Naval Barracks, Keyham. With the exception of the "Impregnable" training ship, the whole of the depots at Devonport are connected by telephone. A party of men from the torpedo school, "Defiance," have carried out the work, under the direction of Mr. Brockman, torpedo gunner. The "Impregnable" will be included in the system as soon as arrangements can be made for moving her head and stern, and thus prevent her swinging with the tide.

Manchester.—On Saturday last the lamps already connected to the mains of the Manchester electric light supply, which have up to the present been used as a simple two-wire system, were disconnected prior to the rearrangement of the mains upon the five-wire system. The lamps were subsequently placed on the various sections of the five-wire 400-volt system with success, and will continue to be run on that system. The number of lamps disconnected from the old system exceeded 10,000; but so great is the demand for electric light that it is expected to be able to have 30,000 lamps on the new system before very long.

Electric Lighting Concessions in France.—The Cahors Gas Company recently asked the municipality to grant it an electric lighting concession, and offered to supply current for public purposes at 1s. 4d. the kilowatt hour, and for private purposes at 1s. 6d. the kilowatt hour. These prices were too high for the municipality, and a committee was appointed to inquire into the prices charged elsewhere in France, and found that the average price charged at St. Etienne, Nimes, Havre, Vannes, Paris (Sector Drouot), and Bayonne, came out at about 10d. per kilowatt hour. The Gas Company has now had the following private lighting tariff submitted to it by the municipality:—10d. per kilowatt hour consumed by each 16-c.p. lamp alight from 60 to 100 hours per month, with reduced charges in the case of lamps burning a longer time each month.

Edison-Bell Phonograph Corporation.—This Company seems to be rather hurt by our remark last week that phonographs, after many years of obscurity, are appearing among street shows, and invite us to inspect the instrument which they are now offering. We wrote from actual observation at the last St. Giles's Fair at Oxford, and in Farringdon-road, and elsewhere. The public, no doubt, get an excellent pennyworth, for the last phonograph which we tried, at a garden party, left nothing to be desired; it is a distinctly better toy than a musical box. Its commercial value can only be measured by its commercial success. We learn that a rental of £10 per annum, with a rebate for additional instruments, is asked, and postal cylinders in cases cost 9d. each. When we hear that 500 instruments are in use in London, or 1,000 in the United Kingdom, for commercial purposes other than street shows, &c., it will be time to consider whether a commercial success is probable.

Brighton Arc Lighting.—Councillor Ballard has been critically inspecting the electric lighting of the Brighton Front, and, as a result, has sent a budget of suggestions to the Lighting Committee. He says:—

I beg to call your attention to the following defects in the electric lighting on the Sea Front at Brighton. 1st, to the inordinate height of the lamps; 2nd, to the waste of light caused by the ornamental supporters of the canopy over the lamps; 3rd, to the uselessness of the canopies over the lamps for the purpose of reflectors. I beg to suggest as follows:—1st, that the lamps should be lowered to about the height where the ornamental part of the lamp-post ends and the fluted part begins. I have compared this with the electric lamps outside the tobacconist's at the Pier, and find that the lamps would then be higher than those at the tobacconist's. 2nd, that the canopies should be upheld by a single piece of iron on the south side, and the present ornamental supports be removed. 3rd, that the present canopies be removed and replaced by a more flattened shape, and a highly reflective enamelled inside surface. The above, although of importance with a view to obtaining the highest degree of illumination, are matters of detail; but in other respects I have to congratulate the Committee on an installation far more liberal than I ever expected, and uperior to anything I have ever seen in Paris or London.

The Glasgow and Belfast Telephone System.—Some four months ago, at a cost of about £20,000, the Post Office laid down a telephone between Glasgow and Belfast. The tariff, however, says a Belfast paper, was so prohibitive, namely, 5s. for three minutes' conversation, that for over two months no business followed. The price was then reduced to 3s., or 1s. a minute, and since this reduction, which took place on the 20th July, there have been six conversations across the wire. One of these extended to nine minutes, thus costing the caller-up 9s. By an arrangement just entered into with the National Telephone Company, there are to be increased facilities for telephonic communication between the two commercial capitals which should lead to extended business. Subscribers can now, if they so desire, get switched on to Belfast from their places of business. As, however, the line to Belfast is on the metallic circuit system, subscribers will require, at trifling addition to their rental, to have their wires on the same principle, so as to ensure good communication.

University College, London.—We have received the syllabus of this College, and are informed that the new engineering and electrical laboratories will be opened for work on October 3rd. "It should be clearly understood," says the syllabus of the Applied Science and Technology Department, "that the education given in this department of the College is not intended to supersede such necessary practical training as can only properly be acquired in the workshop or factory." This warning is repeated more than once, nor is it contradicted by offering workshop instruction as part of the ordinary course. "Students taking a three-year course, and in special cases others, may be

Digitized by Google

permitted, at the discretion of the professor, to work in the laboratory workshop under his direction, making models of apparatus, &c., described and illustrated in their lectures. Any student desiring this privilege must make special application to the professor." Distinct from this workshop, there are the new engineering and electro-technical laboratories, in which we have no doubt much valuable practical work will be done.

The Comparative Cost of Gas and of Electricity.—At the Urban Town Hospital, Berlin, the electric light is in use; the current being generated on the premises, and 1,220 glow and 30 arc lamps being fitted. During the year 1891-2 there were used 1,025,800 ampere hours, and their cost was £1,416. The average cost per glow lamp per hour was 0·1572d. for current and 0·0324d. for renewals, the lamps lasting 600 hours. The average cost per arc lamp was 1·156d. per hour for the current, and 0·252d. for carbons. The prime cost for machines and apparatus was £5,052, and for wiring, &c., £3,124. Taking sinking fund and depreciation, on the former at 12 per cent. and on the latter at 8 per cent., these items would make a total for the year of £856, and taking this into account the hourly cost of the glow lamp would come to 0·2916d., and that of the arc lamp to 2·16d.; while the total annual cost would be £2,272. With gas at 4s. 3·886d. per thousand, the annual cost would have been £2,471. If the current had been taken from the central station, the total annual cost would have been £3,583.

The West End Street Railway of Boston.—The resignation of Mr. H. M. Whitney of the presidency of the West End Street Railway Company is announced. Soon after the consolidation of the Boston lines some years ago, Mr. Whitney undertook the investigation of the various kinds of mechanical traction. Disappointed with the results of careful trials of a storage battery system, and realising the difficulties that the cable would be compelled to contend with in such narrow and tortuous streets, Mr. Whitney was induced to visit Richmond, Va., early in 1888, and witness the operation of the Sprague system. From what he saw at that time he was thoroughly convinced that the only practicable system of mechanical traction for Boston was the overhead electric system, supplemented possibly by a conduit system in the more crowded business streets. He returned to Boston determined to advocate its introduction, and the result of his efforts is well known. The conduit was tried and abandoned, being replaced by the trolly system throughout. Mr. Whitney is to devote his time hereafter to other than street railway interests.

Heavy Gradients Compensator.—One of the most ingenious contrivances for assisting tramcars up and down a short length of stiff gradient is described in the *Engineering Review* for September. The plant has been in successful operation for some time at Seattle, in Washington, U.S.A. For a distance of 1,000ft. there is a gradient varying from 11 to 16 per cent. Two counterbalance weights, aggregating six tons, run on rails laid in a conduit beneath the track. These weights exactly balance an empty car, and are attached to wire ropes running over pulleys. At the top of the gradient, on its way down, the car picks up the rope and, in descending, hauls the weights up, thus checking its own speed, so that the car brakes will hold the load without difficulty. At the foot of the gradient the conductor disengages the rope by means of a hand-lever. Going up, the connection is made automatically, and disengaged in a similar manner. A gradient of 20 per cent. may be readily overcome by means of this simple and admirable expedient. It will be evident that since the action is cyclical the only loss of power is that due to the small friction of the gear and tackle, while the only condition necessary to continuous working is that cars going up the gradient shall alternate with those coming down. In a horse-traction system such a device means humanity; in a system of electric traction it means smaller motors per ton of rolling stock, and a greater annual saving of energy, which would otherwise be spent in raising cars up hill, or in brake-power on the down trip.

The Electric Railway Boom in America.—We have had our own electrical booms in 1882-83 and 1890-91, and their origin is not unknown. Apparently the electric traction boom across the Atlantic has had a somewhat similar basis. According to the *Engineering and Mining Journal* of New York, "A local company is organised to build an electric street railway, say, by the efforts of the manufacturing electric company, which takes all the bonds of the local company, perhaps, or a part of them at least, in payment for the plant furnished. The central company holds these bonds until the local company becomes a going concern, and a favourable opportunity to dispose of them appears, when the transaction is closed. This system of business was made necessary by the very magnitude of the undertakings, especially when such electric installations were a new thing and the identification of the company which wanted to sell them with the local companies or purchasers was in the nature of a guarantee. It was for the interest of the manufacturing companies to follow this policy in order to sell the largest possible number of plants, not only for the profit in the first transaction, but also for the business of furnishing supplies to them ever afterward. The success of the Thomson-Houston and Edison electric companies, now consolidated as the General Electric Company, in building up an enormous business demonstrated the wisdom of this plan, but when the credit system failed, of course the whole fabric tottered, it being impossible to carry the bonds and securities of subsidiary concerns, and no capital coming forward for investment in new undertakings." If electric traction is to be developed in this country by these methods only discredit to the electrical industry will ensue.

Obituary.—We regret to announce the death of Mr. *H.* Weaver, which occurred at Folkestone on Wednesday, September 20th, from heart disease. Born at Shrewsbury on May 5, 1825, Mr. Weaver entered the Electric Telegraph Company in May, 1846, and had charge of various stations in England till 1853. In connection with this Company two submarine telegraph cables were laid between Lowestoft and the Hague, and subsequently two more between Lowestoft and Zand Voort, Holland. This undertaking was managed by Mr. Weaver until 1859, when the Dutch ends of the cables were transferred to the Dutch Government. Upon his return to London, in 1859, he became metropolitan superintendent for the Electric Telegraph Company, and manager of the International Telegraph Company in London, which position he occupied till 1864, when he was appointed secretary to the Electric and International Telegraph Company, and held that position till 1870, when the telegraphs were transferred by purchase to the Postmaster-General, under Acts of Parliament, 1868, 1869, and 1870. The whole of the negotiations for the purchase by the State of the lines, cables and business of the companies represented by him were under his control, he being appointed sole arbitrator. After the transfer of the inland telegraphs to the State, Mr. Weaver took the management of the Anglo-American Telegraph and the Atlantic Telegraph Companies, which position he has held since the January 1, 1870. In addition to being managing director of the Anglo-American Company, he was also director of the Indo-European Telegraph Company, director of the West India and Panama Telegraph Company, and the Western Union Telegraph Company, New York. Mr. Weaver originated the "word" system of counting and charging messages, and introduced it on the Atlantic cables on May 1, 1872. A funeral service was celebrated on Tuesday last, at St. Mary's, Bryanston-square, which was attended by a large number of friends, and the interment afterwards took place in Norwood Cemetery. ——Mr. Thomas Hawksley, one of the oldest members of the Institution of Civil Engineers, died at the age of 86 on Saturday last. Mr. Hawksley's earlier practice lay chiefly in waterworks and gasworks. He was President of the Institution of Civil Engineers for two years, in 1871-2; President of the Institution of Mechanical Engineers in 1876; and was one of the founders and the first President of the Gas Institute. He was elected into the Royal Society in 1878.——We have also to announce the death of Lord Alfred Spencer Churchill, which took place at his London residence last Thursday week, September 21st. He had been ailing for some time, and died at the age of 69 years. He was a great-uncle of the Duke of Marlborough, and, like him, much interested in electrical science. One of his latest inventions, a closed-conduit system of electric traction, is described in another note.

AN EXAMINATION OF PROF. LODGE'S ELECTRO-MAGNETIC HYPOTHESIS.

BY PROF. J. H. POYNTING.

The leaders in Physical Science, impressed perhaps with the responsibility of their position, and fearing that their weaker followers will distort their views, are, as a rule, very cautious in giving us their vaguer speculations as distinguished from the more exact hypotheses which can at once be put into working shape. Yet these less formed speculations are often helpful, even if they only arouse our minds to attempt to disprove them. Still more are they helpful if they aid us in thinking of facts in a more connected way until the finished working hypothesis is ready to take their place.

We owe a special debt of gratitude on this ground to Dr. Lodge for his well-known book on the "Modern Views of Electricity," in which he describes not only the more definite beliefs which he firmly holds, but gives us also any suggestions rising in his mind which seem to give promise of light to guide us in the dark ways of the science. He talks as it were confidentially to us, and though the speculative character of the book makes it by no means the easy reading which the absence of mathematical treatment might lead us to expect, and even perhaps unfits it for beginners, the bold attempts at explanation give it great value to more advanced students. Such students will be brought face to face with many difficulties which they may hitherto not have recognised through haziness of thought. And even where they are unconvinced by Dr. Lodge's attempts to solve the difficulties they will be gainers by the orderly review of their knowledge necessary before they can form a judgment.

The book is built round a central hypothesis of the nature of electric action, which I propose to examine. I shall first give an account of the hypothesis as it appears to me to stand, freed from the details and the wealth of illustration, which, though appropriate, and even necessary, in the original work, make the argument at times rather difficult to follow. I shall then examine the evidence for or against the hypothesis.

We start with that which everyone accepts as the result of experiment and observation, that there are two kinds of electrification with oppositely-directed qualities, and that they make their appearance always in equal amounts. Hence, on their union, the net electrification is zero. Compare this with the case of momentum. According to our experience, as summed up in the third law of motion, we may regard the mutual stress between two bodies as consisting of a *transfer* of momentum from one to the other. A gun at rest is fired. The momentum gained by the bullet and powder may conveniently be regarded as derived from the gun, which, having none to begin with, now has an amount of negative momentum equal to the positive possessed by the charge. In other words, positive momentum is transferred from gun to charge. Or compare with a case of material transfer, as when A lends B a sum of money. Then A and B, after the transfer, are oppositely affected, so that if they both assign their share in the transaction to a third person C the effect on C is zero; or if B re-transfers the sum borrowed to A the net result is zero.

Such cases as these suggest that positive and negative electrification are merely the creditor and debtor sides of a single transaction, the sending out and the reception of something transferred (p. 9). What kind of transfer we must imagine is best gathered from the "ice-pail" experiment, a particular case of the general principle that when induction occurs + and − always *face* each other in equal quantities with an insulating medium between. We may suppose that we have a nearly closed hollow insulated conductor, and that through an orifice we introduce a body having on it a charge +Q. Immediately −Q gathers opposite to it on the inside surface, and +Q is on the outside surface, facing −Q on the walls of the room in which the experiment is made. If, instead of carrying out this electrical experiment, we imagine an indefinitely extended incompressible liquid, and think of merely mathematical surfaces occupying the positions of the surfaces of the conductors, the introduction of Q of liquid within the inner surface would force Q of liquid through each of the two surfaces, and relative to the space between the surfaces, inwards towards the inner surface, and outwards from the outer.

Now, suppose that such an incompressible liquid, to which for the present we need not ascribe gravitation, has an actual existence, that it fills all space with which we are concerned, and that it permeates matter, Let us suppose that in bodies which we term electrical conductors it is free to flow with nothing worse than frictional loss of energy, but that in insulators it has some kind of attachment to the matter, so that in the displacement of one relative to the other—that is, in the strain—energy is stored, and in such a way that it can be regained when the strain is relaxed. We shall call this liquid Electricity. When a displacement occurs, so that some of the liquid is pushed into or out of any conductor, the quantity flowing through the surface from or to the insulator is that which we have hitherto called the charge of electricity on the surface. We must now term it Electrification to distinguish it from the general body of the liquid, which is, according to Lodge, all Electricity. It is important to notice this distinction in studying Lodge's hypothesis. Electricity is the generic name for the fluid all through space, electrification the specific name for that part of it which happens to have flowed in any given disturbance through the surface of a conductor. Thus, if we imagine a conducting sphere A within a hollow conducting sphere B, B having an orifice through whichwe can introduce a wire to charge the inner sphere, say, positively, the gathering of a charge Q on A, is to be regarded as a flowing of some of the all-extensive electricity along the wire into the sphere, which is, however, already full of electricity. Hence Q must be pushed through the surface of the sphere out into the insulator or dielectric. This outward displacement manifests itself as the + electrification of A. As the dielectric is also initially full of electricity Q must be pushed out through every surface in it completely enclosing A. The displacement relative to the air particles stores energy—the energy of the charge. When we come to the inner surface of B, Q is pushed into the substance of B, an inward displacement which we term a negative charge. It is also pushed through the substance of B, but as this substance is conducting, no energy is stored, and only a little is dissipated by the frictional rub, or, perhaps better, the viscous cling. At the outer surface of B there is another displacement of Q outwards into the dielectric—*i.e.*, another positive charge, and energy storing begins again. The pushing out will take place through the second dielectric till we come to the walls of the room in which the action is occurring. Here it will probably end, for the generator of the original charge has probably sucked in the fluid from the walls. There is therefore a confined circulation, and not an infinitely extended pushing out.

Sources of electrification with their connecting wires are evidently to be regarded as turbines working in pipes or channels laid in space, incompressible and fluid electricity filling both the pipes and the space outside them. When the turbines work the fluid runs along the pipes, forming what we call an electric current. When a pipe ends in a reservoir bounded by a dielectric, the fluid presses out into the dielectric, and there stores the energy put into it by the turbine, *minus* that dissipated by the viscous resistance in the pipes and conducting channels.

Prof. Lodge illustrates the connection between the electric incompressible fluid (why not the electric liquid?) and the molecules of matter by a series of ingenious and suggestive models either with cord running through beads or with liquid to represent the electricity. It is hardly necessary here to describe these. Any reader who is not yet acquainted with them should study the original account. It is enough to say that Prof. Lodge can make his models behave like Leyden jars and give the phenomena of charge, residual charge, and oscillating discharge as perfectly as if they were thorough believers in his hypothesis.

I find it somewhat easier to form a picture of the hypothesis by supposing matter to have a sponge-like constitution, *i.e.*, to be permeated in every direction by passages, the pores so dear at one time to the writers on elementary science. These passages

Digitized by Google

are filled with liquid electricity. In every passage or tube, however short, we must imagine a little turbine turning round with the flow through it and never letting any fluid pass without duly turning. In dielectrics there is a spring like the main spring of a watch, attached to the spindle of each turbine so that when the wheel turns energy is stored. In conductors this spring is wanting, and there is only a viscous resistance to rotation. We may think of the source of electrification, machine battery or induction coil, as a large turbine somewhere in the system with a supply of energy behind it dealt out by a motor of some kind or other. When the large turbine works a flow takes place in the system dissipating energy in the conductors and storing it in the dielectrics. When the charging turbine is removed or disconnected from the motor, so that the way is clear for a return, all the wound-up mainsprings return and drive the liquid back through the sponge. We have only to make the turbines with different moments of inertia, with different qualities of lubricator in the conductors, and with different strengths of spring, and different firmness of attachment in the dielectrics, to get varying permeability, electric resistance, specific inductive capacity, and residual charge. We may, perhaps, simplify the arrangement of affairs by supposing that the molecules themselves are the turbines, and then we get a kind of inversion of the hypothesis described hereafter, which Dr. Lodge develops to account for electromagnetism.

In the displacement hypothesis, with a single electric liquid flowing past matter, there is a very serious difficulty. The energy being stored by the flow past the molecules of matter, we might reasonably expect the electricity to pull, or to tend to pull, the molecules with it, and there should, therefore, be a motion of matter along the lines of force in one direction. But instead of this we have a tension, both ways as it were, along the lines of force or flow. There is displacement of matter only in the case of electrolytes, and here it is both ways along the lines of flow, one set of atoms going one way and another set the opposite way. A modification of the hypothesis is suggested by Dr. Lodge to meet this difficulty and to account for the double electrolytic procession. He supposes that there are two constituents of the electric fluid each in general filling half any space, intimately mixed and evenly distributed. The molecules of matter are made up each of two constituents in accordance with the usual view, and one of these is attached to one kind of electric fluid the other to the other. When electric displacement occurs it is really a double flow, the two constituents of the fluid travelling equal distances in opposite directions past each other. The atomic constituents of each molecule move in opposite directions, but not in general very far, so that there is in dielectrics no displacement of the matter as a whole. In electrolytes the displacement continues till separation and repairing occurs, and thus we get a double procession.

We see that in dielectrics the pulls of the two constituents of electricity in the molecules, one on one atom, the other on the other, balance each other. These electric pulls lead to internal stresses within the molecule about which Dr. Lodge does not say anything very definite, but it seems to me that we have to introduce chemical forces here to account for the pull of the atoms on each other, distinct from the electric forces or the pulls of electricity on matter. This dualism is hardly in accordance with the later exposition of Dr. Lodge's ideas, where he appears to identify electrical and chemical forces (p. 84). Perhaps we might as well, while we are inventing a constitution for the ether, make a third or neutral constituent to which all the atoms of matter are attached. We will suppose this neutral electricity to resist extension and compression. We then have electro-positive atoms attached to positive electricity, electro-negative atoms to negative electricity, and all of them to neutral electricity. When an electric displacement occurs, positive ether tugs at one set of atoms, negative ether at the other set, and neutral ether prevents their separation, so that all our forces are of one kind, insomuch as they are forces between atoms and ether. I rather like this neutral ether, but I am afraid Dr. Lodge will not adopt a strange infant into a family already sufficiently large.

But taking the hypothesis as set forth by its author, the mere duality does not much affect the general notion of the nature of electric charge. We must remember that motion of negative fluid inwards equally with that of positive charge outwards gives a positive electrification, so that the explanation of the electrification of a sphere within a conductor already given has only to be amplified by supposing that there is another ethereal fluid displaced in the opposite direction at the same time and throughout the system.

I can imagine the agnostic in ethereal matters protesting here against the multiplication of unknowns and unknowables. I can imagine him saying that his sense organs are only excited by material motions and affections, that his instruments are all material, and only appear to undergo changes of shape, colour, sound—*i.e.*, affections of matter and that he cannot with any certainty get beyond these material affections. He will argue that, as we have no sense affected by ether alone, we can form no adequate conception of the ether; we can only suppose it endowed with material properties, and conceive of it as some form of matter. And it would appear possible to imagine various material ethereal constitutions or connecting machineries between the different portions of matter evident to our senses, all equally accounting for all known facts. When a new fact turned up he would own that probably some of the ethereal machinery would fail to account for it, and so would have to be taken off to the lumber-room for worn-out hypotheses; but the new fact, he would argue, would very likely enable us to imagine new types of machinery to replace some, at least, of the old rejected ones. And probably, till the whole range of physical phenomena was known, it would always be possible to imagine more than one kind of machinery to account for the phenomena known. Probably only when nothing remained to be discovered would there be a single solution, and only then would it be possible to give a single answer to the question, What is ether? And even then we might be wrong, for the ether might have properties in its action on matter quite different from any of which we have material types.

Though our agnostic, when following this train of thought, may be unconvinced by Dr. Lodge's preface, and may urge that the ether is and will probably remain a hypothetical medium, he will, no doubt, adopt some form of hypothesis for working purposes. If he is an ordinary human being, when he studies such actions, as we term actions at a distance, he will prefer to think of the different parts of the acting matter as connected by something continuous, with material properties. Following Boscovich and Faraday, he may extend the atoms throughout space, and give this extension material properties (a special case of this type of hypothesis is presented to us in the ring vortex theory of the Universe); or he may limit the atoms and put in some new connecting machinery to fill up the vacuum he abhors, and this he may as well call "ether." While, therefore, he may protest against Dr. Lodge's "cocksureness" about any particular constitution for the ether, he is bound to examine any hypothesis reasonably presented to see if it is likely to form a good working hypothesis to account provisionally for the observed facts. He would, no doubt, admit that Dr. Lodge's hypothesis is reasonably presented, and it would only be a question with him whether so complicated a constitution for the ether enables him to think sufficiently easily of the phenomena for which it is to account. Leaving him to consider this, we may pass on to the further development of the hypothesis.

So far, we have only been thinking of the properties of electricity at rest. It is true that we have thought of the electricity as being pumped along conductors and as wasting energy in the passage; but this was only a step onwards to a final statical distribution. We are now to concentrate our attention on the pumping stage.

When electricity is in motion in sufficient quantity and for sufficient time, a new set of phenomena come into prominence. Among these are the heating of the conductor, the heating or cooling of junctions, the opposite ionic processions in electrolytes, and the creation of a magnetic field. The heating of the conductor is to be explained, according to Dr. Lodge, as something analogous to frictional, or rather viscous, dissipation

Digitized by Google

of energy. We may think of the two streams of electricity flowing past the atoms of matter, and continually catching hold of them and letting them go again, as a fiddle bow catches hold of and lets go a fiddle string. Thus, some of the energy of flow is converted into vibrational energy of the atoms, that is into heat. The junctional heat phenomena still wait for complete explanation. We may consider that the facts imply that at a junction of dissimilar metals there is a tendency for positive electricity to move more easily in one direction than the other, and, of course, the reverse with negative electricity. A compound bar with free ends will thus tend to be positively electrified at one end and negatively at the other. Suppose, further, that the tendency to separation of electricities varies with the temperature, and we have at once the thermoelectric current in a closed circuit. Returning to the fiddle bow and string used to illustrate the development of heat by conduction, we can see how it ought to work to illustrate thermo-electricity. Suppose a set of parallel strings in a horizontal plane, one half tuned to one note and the other half to another. The one set may represent one metal with its atoms vibrating in given modes, and the other set another metal in contact with it and with its atoms vibrating in other given modes. Now, laying the fiddle bow across the strings after they are set in vibration, if the motion of the bow is always in one direction it illustrates the pushing of one of the electricities from one metal to the other. I have found that when light bits of paper are laid across two vibrating strings of different pitch there is frequently a movement of translation. Unfortunately for the illustration it is sometimes in one direction, sometimes in the other. The paper was not part of Prof. Lodge's book, and knew nothing of the hypothesis it was expected to support. The opposite procession of ions we may think of as the transport of the atoms by the positive and negative electric streams respectively, the connections between the pairs of atoms being broken down and renewed with fresh partners all along the line and continually.

(To be continued.)

THE ELECTRICAL CONGRESS OF CHICAGO.

BY PROF. SILVANUS P. THOMPSON.

One who sits down to review the proceedings of the Chicago Congress of 1893, and to draw an estimate of the work it may have accomplished for the advancement of electrical interests, finds himself involuntarily framing comparisons with the Congresses that have preceded it. Yet if he would rightly estimate its operations at their value, he must at least attempt to dissociate himself from such comparisons. For, in fact, each Congress is individual, not in reality bound by the decisions of any that have preceded it, and possessing no power to bind its successors. Each Congress has possessed distinctive features of its own, and that of Chicago now just closed is no exception. The location, the attendant circumstances, and the internal arrangements, all differed from those of previous Congresses. To begin with, it was the first and only International Electrical Congress held on American soil. Electrical Congresses and Conventions of purely local or only national scope have been held from time to time in recent years in the United States and in Canada. But at such gatherings the presence of a foreigner has been an unusual circumstance, and comparatively little importance has attached itself to any discussion or decision made. In the present case not only were many Europeans present, but the number of electricians from America itself exceeded that at any of the preceding gatherings in the States. And the Congress itself received an indefinable sense of importance to Americans from the circumstance that its decisions would in some way bind and commit the American nation on certain questions hitherto open. The situation in the States of such matters as the decision of a Congress might affect is somewhat as follows: In the International Congress held in Paris in 1881 and 1884 America was represented. Her representatives in the former year accepted the main decision then arrived at to adopt for international purposes the British Association system of units as modified by the addition of the names of the *coulomb* and the *ampere*, and with the substitution of the mercurial column for the old B. A. unit as the standard of resistance. But in 1884 when it was agreed to accept for the length of the mercurial column representing the ohm, the figure of 106cm., the American representatives had been amongst the dissentients, holding that a nearer approximation to the true ohm would be made by an addition of two or three millimetres. How completely they were justified subsequent events proved. But from that day to the present the so-called legal ohm (with the corresponding volt and farad) had never been recognised by the United States Government, which had taken no steps to legalise any electrical units or standards. This is the more remarkable when it is remembered that last year the United States adopted as the legal standards of length and mass, in America the actual *metre des archives* and the *kilogramme* now deposited at Paris at the International Bureau of Weights and Measures. Beyond question the leading electricians of America were prepared to act in concert with European nations. They had watched approvingly how at Frankfort the ohm of 106·3 centimetres was preferred to the legal ohm of 106. They had cognisance of the careful and anxious examination made by the British Board of Trade. They knew how at Edinburgh, in 1892, at the suggestion of Von Helmholtz, the definition of the ohm had been modified so as to express the standard column of mercury in terms of mass instead of those of cross-section. All this facilitated decision, and rendered concerted action more easy. There being no governmental telegraphs in the States, no official interference could prejudice the decisions of the Congress or balk the electricians of America from accepting them. Beside the main question of securing international agreement on the fundamental units and standards, there were a few other topics of American interest. There was the proposal to christen the unit of self-induction as the *henry* in honour of Joseph Henry, its discoverer. There was a suggestion to advise on legislation as to the proper way of describing the candle-power of an electric lamp. There were proposals to name a set of magnetic standards; to settle an international notation of electrical quantities; and to decide on a practical unit or standard of light. Such was the official programme before the Congress, but the unofficial programme was a much wider one. A very extensive list of suitable topics had been circulated many months beforehand, and Papers invited from numerous leading electricians. Keen debates were expected upon the burning topics of the day, and several of the Papers promised were avowedly written to promote discussion. Like the Congresses of 1881 and 1884, but unlike those of 1889 and 1891, which were of an unofficial character, the Congress of 1893 comprised an inner Chamber of Delegates consisting of the official representatives of the several Governments. It will be remembered that, in 1881, the French Government appointed no fewer than 75 French delegates in a chamber consisting of little more than 100 members. In the present case, the United States Government appointed only five, and allotted an equal number to the three great powers, England, Germany, and France, other nations having fewer. The chamber sat with closed doors, but admitted by invitation as visitors, without voting power, a few electricians, mostly German and American, whose knowledge of the subject of units rendered their presence of special value. The Congress at large had, as acting chairman, Dr. Elisha Gray, of Chicago, so well known for his pioneer work in telephony and harmonic telegraphy, and lately for his telautograph. At its first assembling, it elected by acclamation as honorary president His Excellency Dr. von Helmholtz. It has also as presidents of its three sections, Prof. Rowland, Prof. Cross, and Prof. Houston. Its general secretary was Prof. Crocker, who, unfortunately, was only so chosen after the meeting of the Congress. Had he been appointed beforehand, much valuable time that was wasted on preliminary arrangements would have been saved. And here a word of explanation as to the loose character of the arrangements made for the accommodation of the Congress may be recorded. Had the electrical men of the

Digitized by Google

States held the control of affairs, no doubt the whole from first to last would have been carried through in a business-like way, with efficiency, and dispatch, and method. But, unfortunately, since the Congress was supposed to be in some way connected with the World's Fair, the work of preliminary preparation was committed to a semi-official organisation known as the World's Fair Congress Auxiliary, presided over by an utterly incompetent and fussy official of the name of Bonney, who sought to magnify his office by calling together in Chicago no fewer than one hundred and fifty different Congresses on all topics from religion to piano-tuning. Of these there was a large number going on every week; the Electrical Congress week witnessing also Congresses on Astronomy, Spiritualism, Africa, Chemistry and Freemasonry. Persons accustomed to the good organisation of the meetings of the British Association were horrified to find conspicuous by their absence all such features as the daily programme, the reception-room, the printed list of members, and the like. The list of Papers to be read (not in their order), though prepared on the Friday evening for the Press, was not ready for distribution till Tuesday. The rooms chosen both for the general session and the section-meetings were intolerably noisy—opening upon a busy station of the Illinois Central Railroad. And no provision was made for securing proper reports. The daily newspapers of Chicago city made no efforts to give useful reports, and sent reporters destitute of any technical competency, who merely chronicled trivial personalities. On the other hand, great efforts were made by the proprietors of three leading technical electrical journals to produce reports of the Congress with promptness. Such alertness on their part made the incapacity of the daily papers seem even more glaring. This Congress, the only official one of all the series, was treated as though it had no more significance than a Congress on chess-playing. It was entirely ignored by the municipality, and by the prominent citizens of Chicago. If it had not been for the personal exertions of Dr. Elisha Gray, of Prof. Carhart, and of some of the more active members of the American Institute of Electrical Engineers, who at an early date took an active part in foreshadowing the arrangements to be made, the whole thing would have been a melancholy fiasco. Englishmen knowing the difficulties which their American brethren may have to meet from the incompetence of officials who owe their appointments to political influences, can make allowances. What their Continental brethren may have thought of such a discreditable state of things may be imagined. After the opening session of the General Congress, with its speeches of welcome, sectional meetings were held. Section A, on topics of Theory under Prof. Rowland, met next morning only to adjourn, being unable for that day to discover what business there might be for it to transact. Sections B and C, which were respectively devoted to Mixed Theory and Pure Practice, were more fortunate, and held active sessions each morning, and were attended by considerable numbers. The chief discussions, some of which had to be adjourned, were on the subjects of Long-distance Transmission of Power, Multiphase Motors, Phenomena of the Arc, and Ocean Telephony. Prof. Ayrton's Paper on the arc will probably be the most enduring in note of all the Papers read. Mr. Preece's account of his experiments on telegraphing without wires was also well received.

The Chamber of Delegates, under the Presidency of Prof. Rowland, of Baltimore, met usually in the afternoons. It set to work first upon ratifying the fundamental electrical units in such form as to meet with international agreement. There was little dissension as to the actual end to be arrived, but much discussion as to the form. After it had been agreed to adopt as the international standard of resistance the mercury-column ohm 106·3 centimetres in length, there arose a prolonged wrangle as to whether this should be taken as a primary standard or not. Prof. Mascart desired that this material standard should be decreed to be the ohm without any reference to the centimetre-gramme-second system of units from which it is supposed to be derived; just as the international metre is defined as a certain bar of platinum without reference to its supposed relation to the quadrant of the earth's meridianal circumference. On the other hand, Prof. Mendenhall strongly urged that the abstract definition as 10^9 in the C.G.S. system should be retained. Eventually by the appointment of a small sub-committee to settle the wording, a compromise was arrived at which leaves the definition in entire accordance with that already accepted in England, Germany, and France. Similarly with the definitions of the ampere and the volt, compromises were finally voted with unanimity. It was curious to note that M. Mascart, who had stood out on the ohm as the champion of the material standard, advocated equally succinctly the definition of the ampere as an abstract unit without reference to any material way of reproducing it, whether by silver deposit or by some standard gravitational ampere-meter or electro-dynamometer. M. Mascart denied the precision of the silver deposit, and was supported by his Excellency Von Helmholtz. Profs. Carhart and Rowland equally impugned the possibility of getting an absolute reading correct to 1 part in 10,000 by either electro-dynamometer or by tangent-galvanometer, unless in some special research of extraordinary precision. Then the question was raised whether, supposing the ampere should be defined only in terms of the ohm and volt, the latter could be more accurately defined in terms of absolute value than the ampere could be. It was urged that Clark's cells could be made easily to agree to within 1 part in 10,000 to one another. On the other hand, it was doubted whether the absolute value of the cells so agreeing with one another was determined with anything like that accuracy. It was pointed out that the Congress of 1881 defined first the ohm, then the volt, and took the ampere as the mere sequence of these two. Was it well now to reverse the order, and define the ohm and then the ampere, leaving the volt to be defined in terms of that pair of units? Of course in the abstract relations of the C.G.S. system the order was immaterial; but M. Mascart's proposition was to define the ohm in the concrete and the ampere in the abstract; which would necessitate a definition of the volt as that electromotive force which would send the abstract ampere through the concrete ohm. Eventually these matters were referred, as the ohm had been, to the small sub-committee to frame language, and its report, moved by Prof. Mendenhall, and seconded by Dr. Budde, was unanimously adopted. It defines each of the units as an abstract quantity, but adds in each case the practical standard by which in the present state of science the unit may be sufficiently closely represented for legal purposes. To distinguish these units as now defined from the definitions given by previous meetings or Congresses, they are denominated the "international" ohm, the "international" ampere, &c. The wording of the schedules in which are to be described the details of the processes of silver-deposit, for the ampere, and of construction of Clark's cells, was relegated to a sub-committee consisting of Prof. Von Helmholtz, Prof. Carhart and Prof. Ayrton. The definitions of the farad, the coulomb, the joule, and the watt were accepted without much debate as the logical consequence of the three units first decided. Over the proposal to recognise the "henry" as the unit of self-induction there was much discussion. Everybody appeared to be willing to agree to the proposal to adopt the name of "henry" (in honour of Prof. Joseph Henry) in place of the impersonal (and incorrect) name of "quadrant," selected by the Congress of 1889; but no one seemed to be quite ready to define the quantity to which the name was to be attached. It was pointed out that mutual induction must be expressed in terms of the same unit as self-induction. Eventually, an understanding was arrived at. M. Mascart moved, and Prof. Ayrton seconded, the adoption of the name "henry," whilst the exact definition was referred to the sub-committee. The new definition of induction cleverly turns the difficulty that is involved in any attempt to take into account the magnetic properties of the medium, and reconciles the two opposing views. Then came up for discussion the question of the proposed magnetic units. Should the C.G.S. system simply be adopted? Or should a "practical" magnetic system be approved having the 10^8 as a factor in it to correspond to the volt? And what should be the names given to such units? Prof. Rowland objected to any extension of the "practical" system with its eighth and ninth-power exponents, into the magnetic part of the subject; urging, as one reason, that the designers of electromagnetic

Digitized by Google

apparatus do not use anything except the C.G.S. system. He also objected to multiplicity of names. Some attempt was made to secure the adoption of the name of "gauss" for the C.G.S. unit of magnetic field, it being alleged that for want of some such name incorrect designations were sometimes given; as, for example, where the horizontal component of the earth's field is described as being 0·18 *dyne*. A majority of the delegates failed to see the force of this argument. It was moved by Mr. Siemens, and seconded by Prof. Nichols, that the C.G.S. units of magnetism be adopted without names, and this was carried. The question of the scientific designation of the brightness of electric lamps was then introduced. What was a 1,000-c.p. lamp? Was it one that only measured 1,000 in one particular direction? It appeared that certain American contractors, not of the first rank, had been in the habit of describing a certain kind of arc lamp as of 1,000 c.p., which in fact was far from being such. The law being apparently powerless to deal with such frauds in the absence of any recognised definition* of candle-power, decision was asked on the point. It was suggested that lamps should be defined in terms of watts, not of candle-power. American delegates protested that this would not protect the consumer from having imposed upon him an inferior lamp which for the same number of watts gave less candle-power. It was pointed out that under the British Electric Lighting Acts the undertaker cannot prescribe to the consumer what sort of lamp he must use, and leaves the consumer free to use any lamp that is adapted to the declared pressure or current. It was eventually decided that the difficulty being a purely national, and not an international one, arising mainly out of the circumstance that American municipalities have not yet adopted the wholesome practice of calling in some responsible consulting engineer to advise them upon the terms in which their contracts should be drawn up, the Congress could not interfere. But the discussion served to emphasise the uncertainties which exist in the absence of working methods of measuring colour and of a suitable integrating photometer.

Two other questions which were referred by the chamber to the sub-committees received anxious consideration, and were keenly discussed before being reported upon. One of these was the proposal for a system of uniform notation; the other related to the standard of light. The array of symbols proposed by M. Hospitalier was championed by him with ability and eagerness, and was with some amendments adopted by the sub-committee and received by the chamber (but not for official adoption) and ordered to be printed. Some of its details seem open to severe criticism, but if only they could be universally adopted how convenient they would be! The proposal of Drs. Budde and Lummer to adopt as a standard of light the Von Hefner lamp, with its reddish flame of acetate of amyl, was no less emphatically urged. There was no other practical lamp of equal constancy—within 2 per cent.—and the molten platinum standard was not realisable; then why not adopt it as *the* standard? It required much backbone on the part of English, French, and Swiss representatives to resist the vehement plea. But, with the possibility of a simple and better electric standard looming in the near distance, giving a really *white* light of fixed brightness as a standard, it was clear that no proposal for a flame standard would be acceptable, and certainly not this amyl-acetate flame, however excellent may have been the results obtained at the Reichsanstalt. And so the sub-committee, under the presidency of M. Violle, arrived at the inconsequent conclusion that they were not able to report in favour of any standard at present.

All too soon the five days of the Congress came to their end, and the final meeting was held to announce the decisions arrived at, and to thank our American hosts for the courtesy and hospitality with which they had received their guests. Dr. Elisha Gray, in finally responding with characteristic simple dignity, thanked all members present for their help, and begged those who came from foreign shores to Chicago not to think only of its smoke and noise and tall buildings, but of warm hearts praying that they might have smooth seas and a warm welcome home. And so with the inevitable accessories of photographs of groups, of a festive banquet, of a reception by the British Commission, of midnight speeches at the Electricity Building, and of newspaper portraits mainly of celebrities who never came near the meetings, the Chicago Congress vanished into the past.

* An amusing illustration of this inaccuracy is afforded by the way in which the search-lights at the World's Fair are grandiosely described as being of "one hundred and ninety million" and "two hundred and forty million" candle-power. It is known that an arc light of even one million candle-power would require nearly a square foot of *crater* area. Certainly the carbons used in these lamps did not possess cross-sections of a hundred and ninety or of two hundred and forty square feet. They had not even a section of one square foot.

ON METHODS OF OBSERVING ROTATIONS BY MEANS OF INTERFERENCE FRINGES.

BY PROF. GEO. F. FITZGERALD.

The principal difficulty in estimating rotations by direct observation of a rigid body, such as a pointer, is to distinguish between a rotation and a displacement of the centre of suspension. An application of the principle that Michelson employed for separating double stars might be used. In this method the central parts of a mirror are done away with, and only the extreme edges at opposite ends of a diameter employed to send light to a common point where the interference bands are observed. In the case of a galvanometer needle, for instance, as one of many methods, two very small scraps of mirror, parts of the same plane, might be supported on opposite ends of a long pointer, and a divided beam reflected from each might be recombined so as to produce interference fringes. A common motion of the two mirrors, in or perpendicular to their own plane, would not make any difference of path in the two rays, but any rotation would produce a change in the fringes.

It is doubtful, however, whether this would really be much more efficient than the simpler and more easily arranged method of observing, by means of a double-nozzled microscope, both ends of a pointer in a common field of view, and measuring the change in distance between the two images with a micrometer eye-piece. This change is independent of the translation of the pointer, and depends only on its rotation. Photography might be applied to both methods with advantage.

ON THE CHANGE OF ELECTROMOTIVE FORCE OF A GALVANIC ELEMENT WITH THE TEMPERATURE.*

BY A. GOCKEL.

Von Helmholtz has stated that for the combination $Hg, HgSO_4, ZnSO_4, Zn$ the thermal change of a galvanic element can be represented by the algebraic sum of the thermo-electric forces appearing at the different points of contact. The author, in a former work, took this as true also for a Daniell cell; but afterwards G. Meyer (*Wied. Ann.*, 33, 265-288) found, in experimenting on this element, that in general the temperature coefficient of the couple cannot be determined from those of the separate contacts. The author, therefore, resolved to make investigations both with the Daniell cell and with other combinations as arranged by Helmholtz. The results for thirteen different cases bear out Helmholtz's conclusion.

The arrangement of the experiment was as follows:—Four vessels, A, *a*, B, *b*, consisting of test tubes 12cm. high and 5cm. wide, were closed by perforated corks, and each pair connected by 12mm. syphon tubes, in the middle of each of which was a branch for filling it. A and *a* were filled with zinc sulphate solution, and a zinc electrode was placed in each. B and *b* contained copper sulphate in solution and a copper electrode each. The tubes A B and *a b* were filled with zinc sulphate solution, so that there were two Daniell elements, of which one could be heated in a water bath, while the other remained at the temperature of the room. By connecting them in opposite directions the difference in the electromotive forces could be determined. If, on the other hand, the tube A *a* is filled with zinc sulphate solution, the thermo-electric force of the combination Zn (hot), $ZnSo_4$, Zn (cold) can be determined. If the tube B *b* is filled with the same solution we can measure the thermo-electric force of Cu (hot), $CuSO_4$ (hot), $ZnSO_4$, $CuSO_4$ (cold), Cu (cold). By filling the tubes B *b* and A *a* with copper sulphate solution other corresponding combinations can be investigated, and similarly with the remaining combinations.

The measurements were taken with a Thomson's astatic galvanometer of 500 Siemens' units resistance. The tubes were closed with parchment paper. The temperatures varied from 0° to 40°C.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Advertisement Rates, &c., forwarded on application to the Publisher.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday. Renewals of expiring advertisement orders and alterations to standing advertisements must be in Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper Advertisements after Wednesday morning.*

OFFICIAL ANNOUNCEMENTS, AUCTIONS, *and* SMALL ADVERTISEMENTS *accepted up to 4.30 p.m. Thursday.*

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, Limited, who are proprietors of the well-known* "ELECTRICIAN" SERIES *of Standard Electrical Works, and are Agents for all the leading publishing houses at home and abroad.*

"THE ELECTRICIAN" SERIES *at present consists of—*

THE ALTERNATE CURRENT TRANSFORMER IN THEORY AND PRACTICE. By Dr. J. A. FLEMING.
VOL. I.—THE INDUCTION OF ELECTRIC CURRENTS. Price 7s. 6d., post free.
VOL. II.—THE UTILISATION OF INDUCED CURRENTS. Price 12s. 6d., post free.

MAGNETIC INDUCTION IN IRON AND OTHER METALS. By Prof. J. A. EWING, M.A. Price 10s. 6d., post-free.
The same in German, price 8s. 6d., post free.

THE ART OF ELECTROLYTIC SEPARATION OF METALS (Theoretical and Practical). By Dr. GEORGE GORE. Price 10s. 6d., post free.

ELECTRO-CHEMISTRY. By Dr. GEORGE GORE. Price 2s., post free.

PRACTICAL NOTES FOR ELECTRICAL STUDENTS. By A. E. KENNELLY and H. D. WILKINSON. Price 6s. 6d., post free.

DRUM ARMATURES AND COMMUTATORS (Theory and Practice). By F. M. WEYMOUTH. Price 7s. 6d., post free.

THE STEAM ENGINE INDICATOR AND INDICATOR DIAGRAMS. Edited by W. W. BEAUMONT. Price 3s. 6d., post free.

A DIGEST OF THE LAW OF ELECTRIC LIGHTING (1893). By A. C. CURTIS-HAYWARD, B.A. Price 2s. 6d., post free.

THE MANUFACTURE OF ELECTRIC LIGHT CARBONS. A Practical Guide to the Establishment of a Carbon Manufactory. Price 1s. 6d., post free.

ELECTROMAGNETIC THEORY. By OLIVER HEAVISIDE. [*Nearly ready.*

A POCKET BOOK OF ELECTRICAL ENGINEERING FORMULÆ. By W. GEIPEL and H. M. KILGOUR. *Nearly ready.*

SUBMARINE CABLE LAYING AND REPAIRING. By H. D. WILKINSON. [*In preparation*

ELECTRIC MOTIVE POWER. By A. T. SNELL. [*In preparation.*

THE INCANDESCENT LAMP AND ITS MANUFACTURE. By GILBERT S. RAM. [*In preparation.*

Now Ready, in Two Volumes. Prospectuses Free.

"THE ELECTRICIAN" PRIMERS. *Fully Illustrated.*

Price: Stout paper covers, 2s., post free, 2s. 2d. each; strong cloth, 2s. 6d., post free, 2s. 9d. each. Single Primers, 3d., post free, 3½d. Abroad postage extra.

FULL CATALOGUE POST FREE ON APPLICATION.

STEEL-PLATE PORTRAITS

Of Willoughby Smith; W. H. Preece, F.R.S. (President of the Institution of Electrical Engineers); Michael Faraday; Sir John Pender, G.C.M.G., M.P.; Sir William Thomson, F.R.S. (Lord Kelvin); C. H. B. Patey, C.B.; Dr. John Hopkinson, F.R.S.; Dr. Oliver J. Lodge, F.R.S.; Prof. William Crookes, F.R.S.; Prof. von Helmholtz; Prof. W. E. Ayrton; Lord Rayleigh, F.R.S.; Cyrus W. Field; Werner von Siemens; and Sir James Anderson, have been issued as Supplements to "THE ELECTRICIAN."

Copies of these admirably-executed Steel Engravings can be supplied price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price 4s. 6d., carriage paid (U.K.).

"NEW LAMPS FOR OLD."

The reduction in the prices of glow-lamps which took place last week may or may not alter the quality of the lamp to which we have become accustomed, namely, the excellent lamp produced by the Edison and Swan United Company. The altered condition of the business will no doubt to some degree affect the process of manufacture, but whether these lamps maintain their good qualities, in order to compete by their merits with the numerous kinds which will be shortly offered, or whether, being produced at a lower price, a slight but not equivalent lowering of the quality is found, it is certain that many other glow-lamps which will be made in and imported into this country will be of an inferior kind. One of the great difficulties with which the public will be met is that it is impossible, we believe even for an expert, to judge whether the lamp which he may buy across the counter is a good or a bad one. Hitherto reliance has been very properly placed on the *bonâ fides* of the Edison-Swan Company. Of course a lamp can be lit up to see whether the filament is properly suited to any particular voltage, and a purchaser can judge by eye whether it is overstrained or not;

Digitized by Google

but the life, and the inevitable falling off of the candle-power, he cannot even guess. It can only be measured by prolonged observation. In some cases, unscrupulous makers of glow-lamps, before they were finally suppressed by the Edison-Swan Company, have, at all events, in one instance that we remember, deliberately offered 45-volt lamps, or lamps which ought to have been called 45-volt lamps, for use on a 50-volt circuit, and pointed out their great brilliance as a manifestly valuable consideration. Several months will elapse before even experts will be able to judge of the real qualities of the new lamps which will shortly be offered. In the abstract which we are giving from the work of Mr. RAM upon the manufacture of glow-lamps a few of the more important tests of lamps will be found; photometric tests, for example, will be found in our present issue, and wattmeter tests will appear next week.

The sale and manufacture of glow-lamps is as distinct from the supply of electric energy by the supply companies as is the sale of gas burners from the sale of gas; more so, indeed, for many of the gas companies supply, and supply at specially low prices, various gas-consuming appliances. With the exception of the letting of meters, electric supply companies have no concern in the sale of electrical apparatus. In the early days of electric lighting makers of gas burners—and there are, by the way, only a few of these in this country—naturally inquired into the commercial details of their threatened rival, and turned their attention to the price of glow lamps. The 3s. 9d. was so much greater than the price of an ordinary gas burner, and the life of a lamp confessedly so much shorter than that of a gas burner, that without regarding the cost of electric supply, of which little was known, they naturally supposed that the whole of the cost of electric lighting would depend largely on the price of lamps, and it seemed probable that the cost of the lamp would have to be greatly reduced before it could compete with gas. In one sense they were right, for there are really in this country few cases, if any, in spite of the ingenious calculations of several leading authorities, where electric lighting by glow-lamps has been able to compete with a good gas lighting if mere price is alone considered. In the important article by Prof. AYRTON, which we print this week, besides much that is of interest concerning the tests of glow-lamps at the Central Institution, a careful comparison is made between the cost of lighting by gas and by electric light. It appears that it is only under the altered circumstances of cheap lamps, over-running, and supply at 4d. per unit that competition in mere price begins.

It will be evident to all those who have given any attention to the characteristics of the modern glow-lamp, that a reduction in prices must be considered in connection with the so-called efficiency of watts per candle. It is only fair to assume, as we have done on a previous occasion, that the Edison-Swan United Company have considered the best interests of their customers in recommending a certain kind of lamp, which they call a 100-volt lamp, to be run upon a 100-volt circuit. It is generally supposed, but has never been acknowledged by the makers, that the life of such a lamp has been about 1,000 hours. The variation of the voltage of most electric supply companies is, however, so great that no very accurate tests of the life of lamps can be made. The life under a mean pressure of 100 volts, when there is a variation within certain limits, is less than under a constant pressure of 100 volts. There has been no reason to suppose that the Company have suggested that their lamps should be overrun for the purpose of increasing their sales. On the other hand, it appears that in the United States, companies who supply both electrical energy and lamps are frequently in the habit of underrunning their lamps, and of giving their customers a very inferior quality of light, with the view of lengthening the lives of the lamps. It is evident that as the price is now considerably reduced it will pay to overrun lamps, both as regards the cost in mere shillings and pence, and for the sake of the improved quality of the light. M. HOSPITALIER has recommended consumers to smash their lamps at a certain point at which they become unprofitable servants. This is a rather exaggerated view to take, and among the many interesting points brought out in Prof. AYRTON'S article, it is clear that it may under certain circumstances be worth while to send half-used lamps from Eastbourne to Newcastle, the lamps having arrived at the Eastbourne smashing-point, and, still remaining, worth a few pence to canny Newcastle consumers. Prof. AYRTON provisionally recommends that 100-volt lamps be run at 104 volts, or, what is the same thing, 97-volt lamps should be run upon 100-volt circuits. It is probable that the curve of total cost will be found to be so flat at its minimum point, that with no great extravagance we might use 96-volt or even 95-volt lamps for the sake of the whiter light, and at a very slight increase of total cost. Prof. AYRTON, however, already assumes that the life of the lamps may be reduced, for purely economical reasons, to 200 hours, and here we are confronted with the nuisance of continually replacing lamps, consequent upon the perhaps still greater nuisance of frequent sudden extinctions. In large public buildings where many glow-lamps are used, burned-out lamps are often to be seen, and the trouble continually of replacing them is no small matter; while in domestic lighting the sudden failure of a single lamp which has been used for the illumination of a room is felt as a distinct drawback, but one which is to be set off against the many useful conveniences of electric lighting. If, however, the life of lamps really becomes naturally reduced to 200 hours, the use of lamps in pairs will have to be much more common, but such a practice already carried to an unwise extent, at once doubles the cost of lamp renewals, since in most cases a 16-c.p. lamp costs no more than an 8-c.p. lamp.

REVIEWS.

Minutes of Proceedings of the Institution of Civil Engineers, 1892-93. Parts I., II., III. Edited by JAMES FORREST, Secretary. Published by the Institution.

The first of these volumes contains no Papers directly bearing on electrical engineering, unless a "selected Paper" by Mr. A. Brebner on "Relative Powers of Lighthouse Lenses" can be thus included. The Paper is of an intricate character, and the author shows that plano-convex lenses are superior to sphero-convex lenses. The effects of different sizes of flame are considered, and a case in which a flame of 46·55mm. radius, subtends an angle of 4deg. to the nearest point of the lens, is discussed in detail. No allusion is made to electric lights in the Paper, but it may be mentioned that the light-giving part of the arc at St. Catherine's Point is about 20mm. by 6mm., and may be considered as a short flame of 10mm. maximum radius, or a mean radius of about 6·5 mm.

The second volume contains the important Paper by Mr. J. E. Dowson on "Gas Power for Electric Lighting," an abstract of which has appeared in these columns. He made no comparison between the use of town gas and of generator gas, but urged the many advantages of gas power over steam power, particularly for electric lighting purposes. Both the Paper and the Appendix contain a large number of tests giving very full information on fuel consumption. The discussion was comparatively uninteresting, and was used as an opportunity for inventors and others to describe new engines, self-starters,

Digitized by Google

which, by-the-bye, would be of little use in a central station, and the comparison of "Otto" and other cycles.

Prof. Kennedy confined his attention to the subject of the Paper. He had found it was possible to reduce the standing loss of steam boilers which were not making steam, to about 10 per cent. of the whole consumption in all the boilers of a station. He found it difficult to get a load factor of more than 65 or 70 per cent. The ratio which he called the load factor was obtained in this way: he took the number of engine hours per week; he multiplied the hours worked by each engine by its full-load output, and added the products together. He thus found how much the station would have done with the same engines working the same number of hours if they had been running all the time at full load. He compared this with the actual output during the week, and the result was about 65 per cent. The comparison could only be fairly made by figures taken from week's end to week's end, including all the nights and all the Saturdays and Sundays, and so forth. He used non-condensing engines which always gave a test result of 24lb. of steam per electrical horse-power hour at the terminals, which was equivalent to 32lb. of steam per unit. He used boilers which gave 11lb. of steam per lb. of coal, under standard conditions (that was about 9½lb. of steam actually sent to the engines) also on test. He ought, therefore, to use about 3·4lb. of coal per electrical unit delivered; instead of which, in January last, he had obtained at two stations a figure which averaged 5·3lb. That was much better than the average of the year, but he gave the figures as they occurred. He accounted for the difference, which was 1·9lb. per unit, in this way: "First of all, 10 per cent. stand-by boiler loss, 0·53lb. Then he knew from experiment that, working at 65 per cent. load-factor on the engines, he lost about 25 per cent; that was, the steam per electrical horse-power hour would be increased 25 per cent., so that there was 25 per cent. engine loss on 3·4lb., or 0·85lb., and adding that to the 0·53, gave 1·38lb., leaving 0·52lb. still to be accounted for by the load-factor of the boilers, and by all the miscellaneous losses in the station." Mr. Kapp gave some figures showing that with a private electric lighting plant generating 74,229 units during the year 1892, the cost of a unit came to 3·03d.; and Mr. Thomas Preece contributed some particulars of the Dowson gas plant at Morecambe.

In the same volume, Dr. E. Hopkinson's Paper on "Electrical Railways" is published. It occupies only twenty-two pages of the *Proceedings*, and of these, twenty relate to the City and South London Railway. Not only the length but the contents of the Paper are very disappointing. Contrary to the custom of authors of Papers dealing with works of construction, no reference whatever is made to the early difficulties of the undertaking. The engineer of a successful work can always afford to describe difficulties and even failures when he can point to eventual triumph over them. It would have added considerably to the interest of the Paper if some of the stories about the early experiments on this line had been either refuted, confirmed, or better still, authoritatively narrated. We have heard, for example, thrilling accounts of some of the first runs, how the resistances or other part of the gear gave way, and fused, and how the locomotive ran away, the drivers being driven by blazing arcs, showers of molten copper and green fire, to take refuge in the train; and how, as they lay on their faces on the floor of the last carriage, the train flew on to destruction—or to Stockwell! This tale even if modestly edited would have given some life to the Paper.

The space of a page is occupied by a remarkable apology for the use of the jockey pulleys at Stockwell. The condition $V = \sqrt{T/m}$ is to be observed, V being the velocity of the belt, T the tension, and m the mass of unit length of belt. Under these circumstances the author says that a wave on the slack side of the belt "will be stationary in space, tending to maintain the deformation of the belt round the jockey pulley." More mathematics follow, and some data about the belts which appear to fit the formula. The number of mishaps which took place at Stockwell before the belts learned to conform themselves to the formula, and the amount of damage done by hopelessly ignorant and obstinate belts was not recorded. For the purpose of a lecture experiment this theoretical condition might perhaps be maintained long enough to exhibit to an audience, but at a power station, especially at one where the governors appear to be capable of some improvement, this explanation is ridiculous. If the jockey pulleys do not heat, that is sufficient proof that no waste of power is present there, and as long as the belts do not wear out, the power lost in them does not in all probability exceed more than three or four times the loss that would occur with long centres. Some arguments for and against gearless motors are given, and a discussion on the efficiency of the whole system extends over four or five pages. The Paper added but little to the already published descriptions of the line.

In the discussion Mr. Kapp suggested the use of one or two shunt motors at intervals along the line, each driving a fly-wheel, but doing no other work. Fly-wheels 6ft. in diameter, weighing two tons, would deliver 45 H.P. for one minute with a variation of speed from 700 to 500 revolutions per minute. The motors would run all day, taking up power when the load on the line was light, and give out power and lose speed when the heavy strain came on. Mr. Greathead brought some real engineering into the discussion, and gave a good deal of interesting information. He described several diagrams showing the speed, current, volts and electrical horse-power during an up and a down journey of a single train, and the electrical horse-power delivered from the station when seven, nine and ten trains were running. These curves showed the enormous expenditure of power at starting, partly due to work necessarily done in acceleration, and partly to the consumption of current, the useless volts being wasted on the regulating resistances. The great objection to geared locomotives, at any rate in connection with tunnel railways, was their intolerable noise. There was one such locomotive, but it was seldom used, as it could be heard three-quarters of a mile away. A great deal of trouble and loss had been occasioned to the Company through damage to the armatures, resulting, he believed, entirely from the rush of current through the motors at the start. The remedy was found by Mr. Basil Mott, the resident engineer on the line, who wound a number of the armatures with square wire instead of round, and there had been no trouble since with them. Mr. W. W. Beaumont described two forms of gear for connecting the armatures of a locomotive to the car axles for the purpose of enabling the smaller motors to start the train, and thus to avoid the great losses of current and to facilitate starting. These gearings have been recently modified by Mr. Beaumont, and are described in our present issue. The remainder of the discussion did not add much to the general knowledge of the subject; but the author's reply contained a few interesting details. He attributed the breakdown of the armatures to the overloading of the armatures. The wire with which they were wound was covered with two layers of cotton, with a layer of india-rubber between. The india-rubber was destroyed by the heating due to the increased load. The weight of the carriages originally specified was 4½ tons, but the carriages actually used weighed 7 tons. In the correspondence upon the Paper, which is often an important feature of the proceedings of the Institution of Civil Engineers, Mr. A. Campbell Swinton made an independent suggestion of the same nature as that of Mr. Kapp. He suggested the use of a steel fly-wheel, weighing about 6 tons, and measuring 3ft. in diameter and 3ft. wide, running at 4,000 revolutions per minute, and sufficing to maintain 66 H.P. for two minutes with a variation of 5 per cent. of the speed. He proposed to apply such a fly-wheel to a steam turbine at the generating station.

Among the selected Papers in this volume is one by Dr. Preller upon the water-power supply and electric works at Zurich.

The third volume contains no electrical Papers, but it was rather surprising that during the discussion which followed Mr. Sopwith's very interesting Paper on the breakdown of the "Umbria," no allusion should have been made to the use of electrically-driven drills and other portable tools, by which such a repair could be greatly facilitated. Among the selected Papers is one on Wheel Teeth by Mr. A. Sharp, which deserves the attention of all engineers who have to design or construct gear wheels.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 557.)

After the lamps have been sealed up and removed from the pumps, the vacuum is usually tested by means of an induction spark. An induction coil is fitted up in a dark room or closet, and is arranged so that it would give a spark of about ⅜in. in length. The terminals are, however, set at a greater distance apart than this, so that no spark passes. The lamp to be tested is then taken in the hand, and its terminals are held against one or other of the secondary terminals of the coil. If the vacuum is very poor, the lamp will glow all through, even before it touches the coil. If it is better than this, however, but still not good, there will be a glow all through the lamp when its terminals touch the coil. If the vacuum is good enough there may still be a considerable amount of glow, but it will all appear upon the inside surface of the glass, and not at all in the interior of the lamp. The glow in the interior of the lamp in the case of a bad vacuum will be of a blue colour, or if the vacuum is very bad, of a purple colour. In the case of a good vacuum, when there is a glow upon the glass only, it will be blue if the bulb is made of lead glass, but of a green colour if German glass is used. In the case of a good vacuum the glow on the glass is not continuous, but is intermittent, and it only appears in patches, or there may be no glow to be seen at all. With a good vacuum, while one hand holds the lamp to one terminal of the coil, the other hand may grasp the other terminal with impunity; whereas, if the vacuum is bad, a shock will be felt.

The coil test is, however, not infallible. A lamp which shows a poor vacuum may, by being run very bright for a minute or two, be made to show a good vacuum on the coil, no trace of any glow being perceptible. Advantage of this phenomenon is taken by pump-room operatives, if not properly looked after, for getting poor vacua passed as good ones.

The coil test is sometimes applied to the lamps, while still on the pumps, in order to ascertain if they are ready for sealing off. It is more bother than it is worth, however, to do this, as the effect cannot properly be seen except in the dark.

The process of exhausting lamps with mercury pumps is costly and slow. Any mechanical pump which could quickly and with certainty produce a sufficiently good vacuum would be welcomed by lamp-makers. The difficulties in the way of constructing such a pump are many. One great difficulty is that of preventing leakage through the glands and past the piston. Another trouble is that the working parts require lubrication. If oil is used, there will certainly be vapours given off, which will prevent a good vacuum from being obtained. A pump was exhibited in Boston, U.S.A., about three years ago, in which all the difficulties were stated to have been overcome. It was said to exhaust lamps in a far less number of seconds than a mercury pump would do in minutes. The chief point about this pump was that the working cylinder was enclosed in a vacuum jacket. In this way all leakage into the working cylinder was prevented. Oil was, however, used in the pump. As nothing appears to have been published regarding this pump since it was first exhibited, it is to be presumed that its performance did not after all come up to the expectations of the inventors

An ingenious mechanical pump, containing mercury in the cylinder, was patented in 1882 by Gimingham, but the author does not know to what extent it was found to answer.

Pumps for producing the vacua for working the mercury pumps and for flashing, &c., do not require to be of any very special construction. The valves must, however, be opened and closed by direct mechanical action, and should not depend on the pressure of the air. Silk valves will not answer, as they wear out much too quickly, and are not suitable for large pumps. The Packard vacuum pump, manufactured in Brooklyn, U.S.A., is largely in use in America.

The lamps having been exhausted are next tested for voltage and candle-power. For this purpose it is necessary to have a photometer and instruments for measuring the current strength and the pressure. The object of the test is to find at what voltage the lamps must be run in order that they shall be at the right temperature; the temperature, that is, at which they are required to be run, 3, 3½, 4, or other number of watts per candle-power as desired.

In some factories only a few lamps are tested on the photometer, and the other lamps are compared directly by eye with these. Thus, if 100 volt lamps are being made, lamps will be selected by the photometer which run at the required temperature, at, say, 94, 96, 98, 100, 102, 104, and 106 volts. These seven lamps are all hung up in a line. The lamps to be tested are lighted up on the same circuit, and in close proximity to the standards. They are then labelled according as they are found to compare with the standards.

This is not, however, a satisfactory method of testing. The eyes of the tester soon become unreliable, and refuse to see considerable differences in the temperature of the filaments. Darkened glasses may be used to save the eyes from the injurious effects of continually looking at the bright filaments, but they do not make the testing any easier.

Far greater accuracy can be obtained by testing each lamp separately on the photometer. Those accustomed to make photometric tests of lamps in the laboratory will, perhaps, think that it would be impracticable to test every individual lamp owing to the time occupied in making the test. A photometer can, however, be arranged for the lamp factory so that the testing can be done very quickly. A thousand lamps a day can easily be tested on one photometer, provided that the lamps do not differ greatly from each other; that is to say, that 100 volt and 70 volt, or 8 c.p. and 20 c.p. lamps are not all mixed up together. In the laboratory the testing apparatus is conveniently arranged for the observer to be able to read the photometer and the different instruments without moving from his seat. In the factory, however, for rapid testing, the apparatus is arranged so as to be operated by two or three persons. A wattmeter is also required in addition to the other instruments. A wattmeter is not a necessity in the laboratory, as the calculations can be done on a slide rule with sufficient rapidity; but it is essential for factory testing, as it does away with the necessity for making any calculations whatever.

The great trouble in all photometric measurements is the want of a really good standard of light. The light of the incandescent lamp is estimated in candles. Standard candles are, however, of absolutely no use for factory lamp testing, and are of little value as standards under any circumstances.

The most reliable standard of light is the Harcourt pentane lamp (second pattern). It is simply a lamp burning the vapour of standard quality pentane. It is arranged so that the same size of flame, giving a light of one or two average standard candles, is always presented to the photometer. It is, however, more of a laboratory standard than one fitted for constant use with the factory photometer.

For actual use in the factory an Argand burner, burning ordinary illuminating gas with a Methven screen, is preferable, as it requires less attention. The chief trouble in using an Argand burner, even with a Methven screen, is due to the flickering to which the flame is liable if there is the slightest draught. This can, however, be remedied by enclosing the burner in a large box having openings sufficient only for the proper supply of air to the flame. The Methven screen, it is well known, is simply a metal screen with a hole in it of such a size as to only allow a small piece of the centre of the flame to throw any light into the photometer, the light from this piece of the flame being very much more constant than is that of the whole flame.

The position of the Methven Argand standard is adjusted by comparison with the Harcourt standard, and can be checked by it as often as is thought necessary. If the lamp factory has a separate laboratory, with a photometer and testing instruments, it is more convenient to test a lamp in the laboratory, using the Harcourt standard, and then to give the

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved

Digitized by Google

same lamp to the testers in the factory testing room, and see if their test of it agrees with the laboratory one. A convenient way of keeping a check on the testing is to keep one or two lamps to be always tested first whenever the photometer is used. As long as these standardised lamps always test the same it may safely be assumed that the whole apparatus is in good order.

It is not intended here to go into the matter of photometry and lights standards generally, as there are already works upon the subject. An excellent one is that by Mr. W. J. Dibdin, entitled "Practical Photometry," which, although it deals chiefly with gas-testing, contains much information, useful also to the incandescent electric lamp tester.

In testing incandescent lamp the object, as already menioned, is to find what difference of potential must be applied at the terminals of the lamp in order that it may be maintained at a definite temperature or efficiency in watts per candle-power. It is therefore necessary to light up the lamp and ascertain the amount of power it is taking, and then see if it is giving the required amount of light for that amount of power. If the lamps are to be run at 4 watts per candle-power, then for every 4 watts supplied to the lamp it should give a light of one candle. If the lamp when lighted up is found not to give as much light as one candle for every four watts, or is found to give more than that amount, then it must be run brighter or duller by applying a greater or less difference of potential until it attains the required degree of brilliancy. When the adjustment is found to be correct the voltmeter indication is read, and the number of volts registered is the proper voltage for that lamp.

This system of testing, which was introduced by Mr. Swinburne, is the only correct one. It is obvious that if the lamps are tested at a fixed voltage or candle-power they will vary in brightness and efficiency (watts per candle-power) unless they are exactly alike in every particular, whereas by this method they are tested at a fixed brightness and efficiency, and the voltage and candle-power are assigned in accordance therewith. The way in which the author has used the method in the lamp factory will now be described.

The photometer table is at such a height above the floor that the lamp and the photometer disc are on a level with the eyes of the observer when sitting comfortably in a chair. The gas lamp with its Methven screen and the disc box are at the right hand end of the table, the lamp under test being on the left hand of the observer. The photometer bar is graduated directly in candles, the zero point being immediately below the disc. The candle-power graduations are proportional to the square of their distance from the zero line.

The lamp is carried in a frame which can be moved to and fro along the photometer bar by the observer at the disc. The lamp holder is also capable of being raised or lowered and rotated. There is also fixed to this frame another bar, also divided into candles, but having its zero mark at the lamp end. This bar slides backwards and forwards with the lamp frame, and the observer at the photometer is therefore able to read the candle-power of the lamp by the indication on this bar at the zero line immediately below the disc, and does not have to look along the bar to where the lamp happens to be in order to get the reading. This is a great convenience, as the observer does not get the light of the lamp into his eyes, as is the case in the former method.

The wattmeter is fixed on a shelf just behind and above the disc box, so that its indications can be readily seen by the observer at the disc, the scale of the instrument being an upright one, and not one that has to be looked down upon.

There is a large screen all round the disc box, so that the observer at the disc does not see any light except that upon the disc. No light from the lamp under test or the gas lamp can fall upon his eyes. The watt-meter scale is illuminated sufficiently by a small incandescent lamp run very dull. The scale of candles on the movable photometer bar being large and on a white ground can be read by the small amount of diffused light from the lamp under test. In this way there is no light which can upset the eye of the observer.

The switch and variable resistance for adjusting the current as well as the handle for moving the lamp to-and-fro are fixed in a convenient situation for being worked by the observer. The voltmeter (and ammeter, if used) is situated on the other side of the screen surrounding the observer, and is read by one of the assistants. The method of working is as follows:

The tester-in-chief sits at the photometer. In this position he can see the disc box, the wattmeter scale above it, and the candle-power scale below it. He does not see either the lamp under test or the standard gas burner, nor yet the voltmeter nor ammeter. He has the control of the current and the motion of the frame containing the lamp under test. There are two assistants on the left hand of the tester, one on each side of the photometer table. The lamps before being brought into the photometer room have each had a small label stuck upon the neck.

Assistant No. 1 puts a lamp into the clip or holder in the movable carrier. If the lamps are supposed to be 16 c.p. ones the tester sets the lamp at the distance for 16 c.p. by the scale in front of him. He then turns the current on and brings it up until there is a balance upon the screen. He then looks up at the wattmeter scale to see how many candles the lamp should be giving for the amount of power it is taking. If the wattmeter indicates 16 candles, he tells assistant No. 1 to read the voltmeter, and whatever the number of volts happens to be that is the voltage of the lamp.

Supposing, however, when the lamp is giving 16 candles that the wattmeter indicates, say, a little over 17 candles. The lamp in such a case must then be run brighter until its actual candle-power agrees with the indication of the wattmeter. As the lamp is made brighter there is, of course, more power spent in the filaments, and consequently the wattmeter indication also rises, but, as the intensity of the light increases much faster than the power, the actual amount of light will agree with the wattmeter indication at about, say 18 candles. The balance being obtained the voltameter is read by assistant No. 1. The current is turned off the lamps, and assistant No. 2 takes it out of the holder and writes the voltage on the label, while assistant No. 1 puts the next lamp into position. If the candle-power is also to be marked on the label the assistant can ascertain its value for himself by noting the position of the lamp carrier or the fixed candle-power scale.

As most electrical measuring instruments take a perceptible amount of time to come to rest after the current is turned on, it is necessary for rapid testing that the instruments be not allowed to return to zero between the testing of each lamp. For this reason, instead of turning the current off the whole apparatus it is simply switched off the lamp just tested to another lamp of similar size located in a convenient place for giving light to the assistant testers for writing the labels and fixing the new lamp in position. The next lamp being in position, the current is switched back again, and the instruments quickly arrive at their readings, and do not oscillate as they would if they had started from zero. The instruments must, of course, be so constructed that they may be left continuously in circuit without their accuracy being impaired by heating.

The photometer room is necessarily quite dark, and painted a dead black so as not to reflect light. It should, however, be of ample size. It is absurd to locate the testing apparatus in a room in which there is hardly space to turn round, as is frequently done. It is also advisable to arrange for proper ventilation. It is not necessary, in order to keep out daylight, that the room should be hermetically sealed after the manner of the average photographer's dark room.

The tester should be in the dark room for at least 10 minutes before testing, in order that his eyes may get accustomed to the subdued light. On no account should he look at the lamp while testing, or his eye will be unreliable for some time afterwards. There may, however, be a piece of dark neutral tinted glass in the screen on either side, so that he can see the lamp and the flame of the Argand burner without any danger of his eyes being effected. The Argand burner must be lighted 10 minutes or more before it is required, as it may not give the proper amount of light until the chimney and other surroundings are at the normal working temperature.

"NEW LAMPS FOR OLD."

BY PROF. W. E. AYRTON.

In a Paper that will be found in Volume VII. of the *Proceedings of the Physical Society* for 1885* it was pointed out, perhaps for the first time, that the proper potential difference to be employed with glow-lamps in order to obtain the greatest number of candle-hours for a given amount of money expended on lamp renewals and on coal depended on the cost of a lamp and the cost of power in the particular place, and that the most economical value of the potential difference could be found by a geometrical or by an analytical method, examples of the application of both of which to the lighting of the Finsbury Technical College were given, using the best information available at that time regarding the life of lamps when used with different potential differences.

A Paper on the same subject followed shortly afterwards from the pen of Dr. Fleming, and later on in 1888 a lengthy communication on the maximum efficiency of incandescent lamps was communicated by Mr. Howell to the American Institute of Electrical Engineers in which was repeated at considerable length the arguments and the graphical method that were contained in the Physical Society's *Proceedings* for 1885.

The numerous examples given by Mr. Howell of the application of the graphical method to practical cases did not advance the matter much, seeing that the five-years'-life tests, which he stated had been carried on in the Edison laboratory, had been made on lamps which glowed continuously for 6,000 hours, never using more than 4 watts per candle, or glowed for 1,000 hours when no more than 3 watts per candle were employed. For these excellent lamps, stated to be in continuous use in America eight years ago, have failed to cross the Atlantic in more years than it takes days for an ordinary lamp to accomplish the journey.

Later on it began to be recognised that a mere comparison of the watts per candle expended when different potential differences were maintained at the terminals of a lamp at the commencement of its life, with the number of hours that the filament would last before it broke, when the various potential differences were respectively used, did not enable a determination of the most economical potential difference to be arrived at. For it was noticed that there was a serious diminution of the light emitted as the lamp grew older, even when the normal potential difference was maintained, and it was suspected that the curve of diminishing light had possibly a very different shape with a high-potential difference from what it possessed when the normal potential difference was employed.

This deterioration of a lamp with time also led many writers to prove, and possibly a stray user of lamps here and there to grasp, that the most economical life of a lamp was ended long before it ceased to give out light, the economical life being the shorter the dearer the electric power and the cheaper the initial cost of the lamp.

But the characteristic fondness of people to stick to old friends that have served them, which made Frederick the Great buy back one of his old three-cornered beavers at a princely price, and which prevents lesser mortals parting with their hats even when they have acquired the epithet of shockingly bad, renders the public quite oblivious to the fact that the curve of the total cost of a candle-hour has a minimum ordinate at some comparatively short number of hours. If the lamp breaks he will replace it, if it becomes too dull for his needs he will grumble at the fickleness of electricity and buy another lamp, but that a particular time should be called the "smashing point," as if at that point he had to remove an apparently good lamp from its socket, and to put his foot on it, was really too theoretical and ludicrous, thought the economical householder.

Some eighteen months ago I suggested in lectures to my students that the difficulty might be overcome by the establishment of an agency to buy up lamps which had been run for three or four hundred hours at places where electric power was dear, for example, at watering places on the south coast, and to sell them to places where power was cheap, as at Newcastle. "Taking coals to Newcastle" has long been a proverbial expression of folly, but taking half-used lamps to Newcastle, had the price remained at 3s. 9d., might have become a trade showing wisdom, for buying for 2s. a 3s. 9d. lamp that had been run for, say, 300 hours at Eastbourne where power used to be over a 1s. a Board of Trade unit, and selling it for 2s. 6d. at Newcastle, where power was 4½d., would have been a profitable transaction for both seller, buyer, and agent.

Subsequently another solution of the difficulty occurred to me, and one that might lead possibly to even greater economy than could ever be obtained by discarding lamps at the proper time when they were run with the normal potential difference—and that was to use a higher potential difference. For then the lamp would dull sooner and the user would discard it without reference to curves. If, then, a potential difference could be experimentally found, such that the useful life of the lamp at that potential difference was even greater than the strictly economical life when the normal potential difference were used, two ends would be attained.

Therefore, more than a year ago arrangements were commenced at the Central Institution to make daily measurements of the light and current when various groups of lamps, all identically the same at the start, were run with certain absolutely constant potential differences; and some months back, when the different automatic regulating and recording apparatus had been constructed and got to work in a satisfactory fashion, three sets of 100-volt Ediswan lamps were started, running at 100, 102, and 104 volts respectively, the potential difference being automatically kept constant at each of these values, with no greater variation at any time than a very small fraction of a volt. Very interesting results have been obtained, such as the *very considerable increase* in the light given out by each set of lamps, and the marked *diminution* in the watts per candle during the first 100 hours of running, a phenomena known doubtless by the makers to occur with the modern Ediswan lamps supplied us for this investigation, but I think unknown generally to the users of glow lamps. In fact the construction of the modern lamp has been so modified that the small hump which has been noticed to occur after many hundred hours of running in the life curve of lamps, whose filaments were made of bamboo and flashed by the wet process, has been much magnified, and made to occur in the beginning of the life curve.

The details of these results and the bearing the curves we are obtaining have in deciding the most economical potential difference to be employed for different prices of power, will be published in due course, but, as the price of Ediswan lamps was dropped on Thursday last from 3s. 9d. to 1s. 9d. per lamp, it is important to at once point out that higher voltages than hitherto used must in future be employed to obtain maximum economy with glow-lamp lighting.

For let us suppose that electric energy is supplied at 6d. a unit—this is, of course, much lower than private houses pay in many districts of London—and let us suppose that a 100-volt 8-candle lamp when supplied with 100 volts will give an average of 7½ candles for 600 hours with an expenditure of 42 watts. This is a very favourable estimate of the behaviour of a lamp running for 600 hours, but I take this favourable case and the low price for power in order to emphasise the fact that even under these conditions 100 volts is not the proper potential difference to use with a 100-volt lamp. Then the candle-hours produced will be 4,500, the watt-hours expended 25,200, the value of this energy 151d., the cost of the lamp 21d.; and, therefore, the cost of 100 candle-hours will be 3·82d.

Next let us suppose that the same lamp is run at 104 volts, then since the light, as has been shown, varies as the seventh power of the potential difference* the light of this 8-candle lamp will be over 11 candles. Say that this lamp will give at the 104 volts an average of 10½ candles for 200 hours, with an expenditure of 44 watts. This my tests show is understating the value of the lamp so used. In 600 hours three lamps will be employed, at a cost of 63d., as the lamp is renewed after 200 hours; the lamp hours will be 6,300; the watt hours 26,400; the cost of the energy and the three lamps together 221·3d.;

* "The Most Economical Potential Difference to be used with Incandescent Lamps."

* *The Electrician*, July 15th, 1892.

and the cost of 100 lamp hours 3·51d., or about 9 per cent. less than before. Actually the saving of using 104 volts instead of 100 will be distinctly greater, for I have intentionally over-valued the running of the lamp at 100 volts and under-valued its running at 104 volts.

Next let us consider places like Eastbourne, Hastings, and Northampton, where electric energy now costs 9d. a unit; then with the same conditions as before we find that when a potential difference of 100 volts is employed the cost of the energy for 600 hours will be 226·8d., the total cost, including the one lamp 247·8d., and the cost of 100 candle hours 5·5d. Whereas when a pressure of 104 volts is maintained, and three lamps are used in the 600 hours, the cost of the energy becomes 237·6d., the total cost including the three lamps 300·6d., and the cost of 100 lamp hours 4·78d., representing a saving of over 13 per cent. And as explained before, the actual saving obtained by using 104 volts will be considerably greater than this.

Indeed, if we even assume that the lamp run at 104 volts, and giving 10½ candles, is replaced every 150 hours, while the one run at 100 volts is supposed to produce an average of 7½ candles for 600 hours, the total cost of 100 lamp hours in the former case only comes out as 5·1d., or about 10 per cent. less than in the latter. This reasoning becomes even more forcible in the case of 16-c.p. lamps, since the cost of a lamp is the same, 21d., while the expenditure of power per lamp is increased from 42 to 64 watts, so that the cost of lamp renewals form a less fraction in the total cost of lighting. Hence, *a fortiori*, a pressure of 104 volts is more economical to use with 16 candle 100 volt lamps than 100 volts.

Clearly, then, higher pressures must be employed for lamps than formerly, especially in 8d. or 9d. districts; or, as a householder cannot alter the potential difference supplied to him, he ought, when purchasing new lamps, to order those marked for a lower pressure than the stated pressure furnished him by the supply company. Exactly how much lower should be the marking of the lamp to obtain maximum economy for each value of the Board of Trade unit I shall not be able to state until the experiments being carried on in my laboratories are completed; but for a house provided with 100 volts, direct current like my own—which means, as seen from the recording voltmeter, that the Company, greatly I think to their credit, furnishes a nearly constant pressure of 101 volts during the 24 hours—I shall provisionally recommend the use of lamps marked not higher than 97 volts. And, assuming that the amount of light previously obtained was sufficient, then these 97-volt lamps might be chosen of 6½ c.-p. and 13 c.p. to give, respectively, about 8 and 16 candles when run at 101 volts.

The increased brightness of the filament will lead to no practical difficulty, since those who might object to this have already clothed their incandescent lamps in such thick coats that the poor lamps can do little more than keep themselves warm. The higher efficiency at which the lamps will be run will cause less heat to be generated for a given amount of light, a change that probably few will object to.

Many rosy comparisons have been made by electrical engineers of the cost of lighting by electricity and by gas. From the results, however, of a very extensive and accurate series of tests made in my laboratory, about a year ago, on the cost of lighting with a great variety of gas burners, governed and ungoverned, for each different gas pressures varying slowly in some cases from ⅛in. to 3in. of water, I am able to give a comparison which I trust has no bias either on the electrical or on the gaseous side.

Of all the burners my students tested the best governed was the 8-candle Bray's burner for street lighting. With that burner the cost per 100 candle-hours did not sensibly vary for any pressure of gas from ½in. to 3in. of water; and cost, with gas at 3s. a thousand cubic feet, 1·82d. A very good burner was Sugg's 16-candle No. 5 table-top governed. The governing for varying gas pressure we did not find as perfect as with the previous burner mentioned; but at a pressure of about $1\frac{1}{10}$in. of water, where we found the economy greatest and the light exactly 16 candles, the price of 100 candle-hours was only 1·29d. Leaving on one side our tests on large gas burners like the Wenham, which do not, of course, give a light comparable with that of an 8 or 16-candle glow-lamp, and our tests on various Welsbach mantle lamps, whose life histories I shall describe on another occasion, the most economical gas burner we tried was a Sugg's No. 1 London Argand. At a pressure of $1\frac{2}{10}$in. of water that burner gave a light of 22½ candles with a cost per 100 candle-hours of only 1·03d., gas, as before, being taken at 3s. per 1,000 cubic feet, but no allowance being made for the renewal of lamp chimneys, an item of expenditure that can, however, be rendered very small with care.

Let us compare with these prices the cost of using a 100-volt 16 candle lamp, at 104 volts, and renewing it after every 200 hours. The average light we may take at 21 candles, the watts at 66; hence, if we take 4d. per Board of Trade unit, the cost of energy in 200 hours will be 52·8d., the cost of the lamp 21d., the total cost 73·8d., the candle-hours 4,200, therefore the cost per 100 candle-hours will be 1·76d.

The price is less than the cost of lighting with the Bray's street-lamp-governed burner, referred to above, and, of course, much less than the cost of lighting with cheap ungoverned burners, where the cost of 100 candle-hours may easily reach 3d., or more, but it is not as cheap as using Sugg's governed table-top burners, nor is it nearly as cheap as using Sugg's London Argand burners if the pressure with the latter be not allowed to fall below about $\frac{7}{10}$ths of an inch.

In this article I have considered only the effect produced by the reduction of the price of English lamps to 1s. 9d., and I have not dealt with the result of the introduction of foreign lamps at probably lower prices. The Westinghouse stopper lamp sells in bulb, for example, in America, for 1s. 1d., and if the lamp be returned with only the filament broken 5d. is given back, so that the actual cost to the large consumer is only 5d., or not much more than one-third of even the price to which English lamps were reduced last week. The life history of the Westinghouse stopper lamp, and of all the other important American types when run at their normal pressures will be known to the world before the end of the year; for prior to my departure from Chicago we had started, mainly through the energy of Prof. Thomas, tests of about 1,000 specimens of glow-lamps on a basis which many interviews with representatives from the various lamp companies had secured general acceptance.

ON A NEW FORM OF VARIABLE POWER-GEAR FOR ELECTRIC RAILWAYS AND TRAMWAYS.*

BY W. WORBY BEAUMONT.

It is a matter of great importance on electrical railways and tramways that the maximum steam-engine power at work in the generating stations should be as little above the mean load as possible. It is found on electrical railways now at work that there is a great waste of power, and therefore of fuel, in consequence of the large consumption of current in getting the trains into motion by motors attached directly to the axles. On the South London Railway it is found that the power employed electrically in over coming the inertia of the train is from 25 to 50 and 60 per cent. greater than that required to keep the train going.

Mr. J. H. Greathead, M.I.C.E., the engineer of this railway, has shown that if this could be avoided from 20 to 30 per cent. of the engine power which must under present conditions be kept running might be shut down. The author showed this by diagrams representing the variation in the consumption of power in the working of this railway, as given by Mr. Greathead.† For several reasons the employment of geared locomotives is undesirable on railways, although single-reduction gearing is most generally adopted for tramways, and probably will remain best for that purpose. The noise made by high-speed gearing and the wear are both objectionable, otherwise a geared locomotive offers the means of overcoming, to some extent, the losses referred to.

In the Paper the author showed how an intermediate course could be adopted which would remove the loss of power at the generating station. The electric motor is placed directly on

* Paper read before the British Association in Section G.

† *Proc.* Inst.C.E., Vol. CXII.

Digitized by Google

the driving-axle, but is reduced in size and power to more nearly that of the mean horse-power required on the road. This, for the greater part of the journey of a train from station to station, drives the axle upon which it is placed, at its own speed, just as those do which are now upon the South London Railway. The motor is, however, on a hollow spindle, which drives the axle, when starting a train, through the medium of a compact double clutch containing one pair of epicycloidal reducing wheels. The clutches are operated by electro-magnets in one case, and by fluid pressure in another.

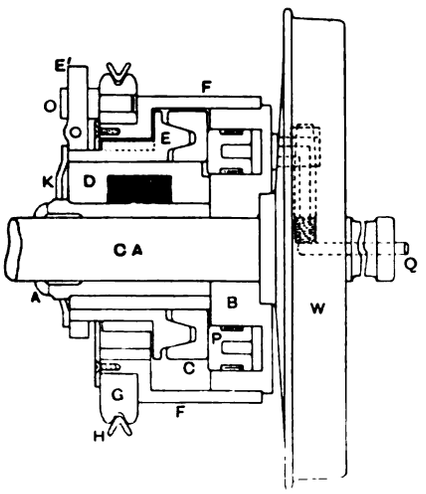

FIG. 1.

In Fig. 1 the gearing is shown as operated by fluid pressure, and arranged as for a locomotive for direct driving. On the axle C A is fixed a disc B, containing an annular "cylinder," or rather chamber, in which is an annular piston, P, which, by admission of oil, under pressure, or air from the continuous-brake cylinders, is caused to press, when necessary, against the gripping ring C. On the end of the motor shaft A is fixed an eccentric, D, which gives a gyrating motion to the toothed ring

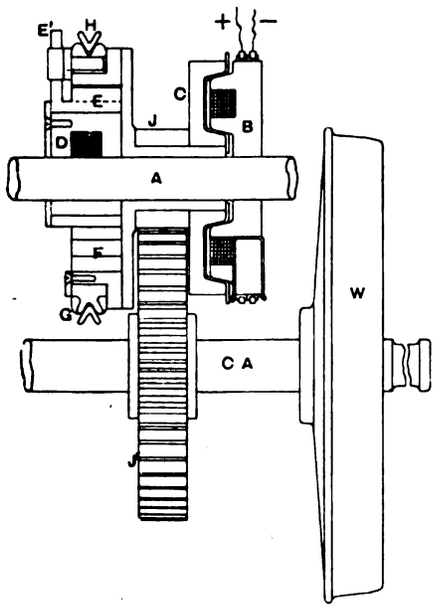

FIG. 3.

E. This correspondingly gives motion at a slow rate to the gear ring F, which is fixed to the disc B. Upon a projecting part of the internal gear ring is a bridle with an arm, E'. This arm is free to slide in a bridle, O, pivoted in a ring, G. The ring G is either permitted to run free or is held fast by parts which constitute a brake clutch, of which only the ring H and levers L are seen.

When it is desired to start a train the ring G is held fast by this apparatus, and O becomes a fulcrum, about which E' with the ring E gyrates. The locomotive axle is then driven by the wheel or ring F at one-fifth the speed of the motor, or a power ratio of five to one. This is required for a few seconds at each start. The inertia of the rest of the train having been overcome, the ring G is set free, and fluid under pressure admitted at Q, thus pressing the ring C upon E. This fixes the whole of the working parts of the gear, and couples the motor shaft and locomotive axle, so that the latter is direct-driven. The motor can thus run idle, driving nothing, or it may drive the axle at one-fifth of its speed, or at its own speed. When running at normal speed the whole of the gear described runs as one solid

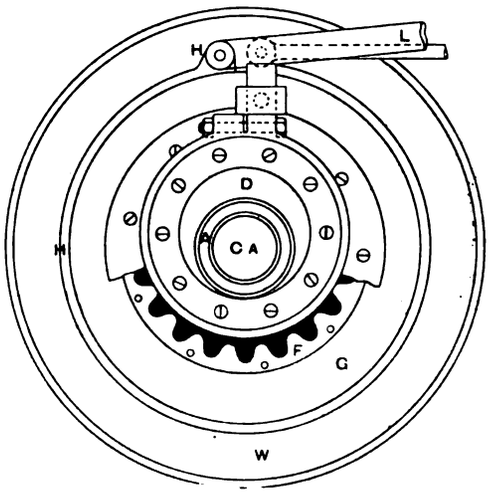

FIG. 2.

piece, and only works for starting a train or getting up-hill. A breakdown would leave the locomotive in the condition of a gearless engine.

The arrangement of the gearing for tramcars, when single reduction gear is employed, is shown in Figs. 3 and 4. In this the motor shaft A carries a disc electromagnet, B, which has as an armature a disc, C, on the boss of the pinion J, which gears into the wheel J' on the car axle, the ratio being four

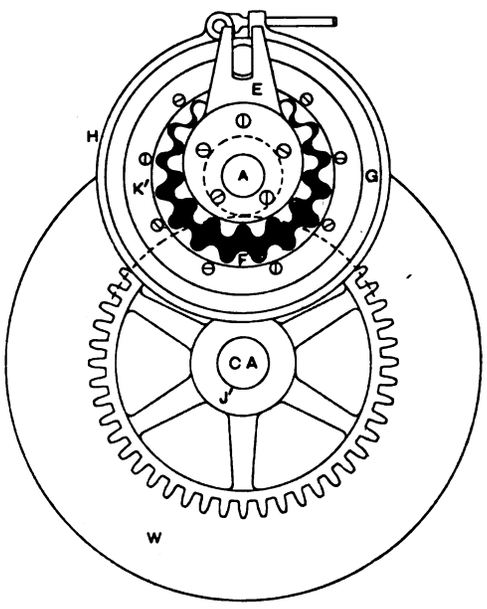

FIG. 4.

to one. The epicycloidal gearing is very similar to that in Figs. 1 and 2, and gives, as shown, a speed ratio of five to one. With this arrangement a motor of 15 H.P. would be ample for any tramcar, instead of the 30 H.P. now used. The motor in starting may run idle, or may drive the car axle through the epicycloidal gear and single reduction gear at, say, a ratio of twenty to one, or by passing a current into the coils and by energising the magnet B, the whole apparatus runs solid on the motor shaft, the gear ratio then being that of the single-reduction gear of four to one.

AN AIR PUMP, WHICH CAN BE WORKED EITHER AUTOMATICALLY OR BY HAND, IN WHICH THE WORKING FLUID MAY BE SULPHURIC ACID, MERCURY, OR ANY LIQUID HAVING A SMALL VAPOUR PRESSURE.*

BY J. J. THOMSON, PROFESSOR OF EXPERIMENTAL PHYSICS, CAMBRIDGE.

In some experiments on the discharge of electricity through gases I had occasion to prepare tubes which should be free from mercury vapour. The safest way of doing this seemed to me to be to get rid of the mercury in the pump. I accordingly fitted up a pump in which the mercury was replaced by sulphuric acid.

As the arrangement adopted for this pump readily admits of its being made automatic, and as sulphuric acid has the advantage of being very much cheaper than mercury, it seems possible that the pump may be convenient for other purposes than the one for which it was designed.

Any fluid which has very little vapour pressure can be used in this pump; mercury can be used in this just as well as in the ordinary form of pump. The arrangement of the pump is represented in the diagram. The vessel to be exhausted is attached by an air-tight connection to A. The end B is attached to a three-way tap, so arranged that when it is turned one way B is open to the atmosphere through a fine nozzle T, while when the tap is turned another way, B is connected to a water pump or other convenient means of producing a fairly low pressure. The extremity K is also connected with this pump.

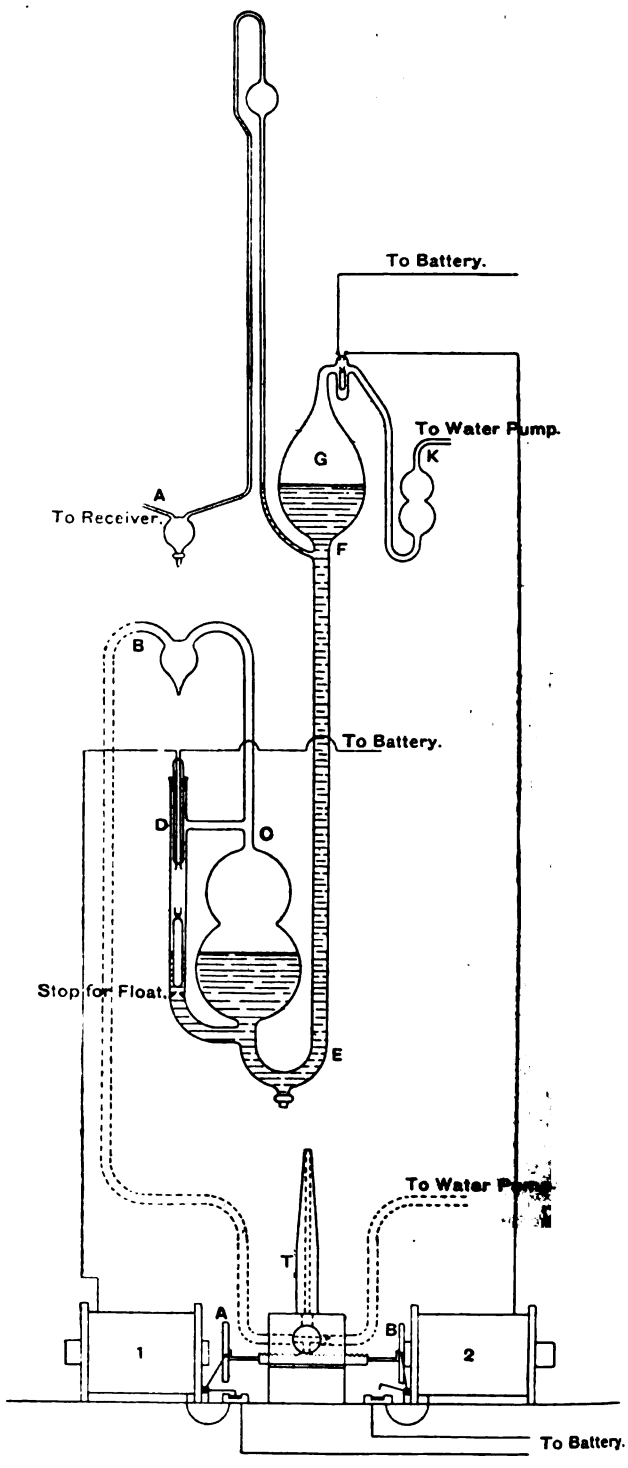
I will first describe the method of using this pump when worked by hand.

The air is partially exhausted by means of the water pump. To do this the three-way tap is turned so as to cut off the communication between C and both the atmosphere and the water pump. The air is removed through K by the water pump, the air from above the acid in C bubbling up through the acid in the tube *ef*, and escaping through K. When a fair vacuum has been got in this way the three-way tap is turned so as to connect C with the atmosphere. The pressure of the air on the top of the acid forces the acid up the tube EF into the bulb G, which it fills, driving the air before it out through K, whence it is carried away by the water pump. When the acid begins to flow over the bend K, the three-way tap is turned so as to put C in communication with the water pump; this reduces the pressure in C, and the acid flows back and falls below F, when more air rushes from the tube to be exhausted into the bulb. The three-way tap is then turned so as to put B in communication with the atmosphere, when the acid again rushes up into the bulb driving the air before it.

By repeating this process the amount of air in the bulb to be exhausted is continually reduced. It will be seen from the preceding description that all the experimenter has to do is to turn the three-way tap at the proper time, the rest of the work is done by the water pump.

To make the pump automatic, all that is necessary is to use some mechanical arrangement by which the pump itself can turn the tap at the right instant. This can be done by fixing to the three-way tap a handle to which two pieces of iron are attached. Two electromagnets (1 and 2) are placed near these pieces of iron in such a way that when 1 is excited the piece of iron is attracted to its core, and the handle of the tap turned so as to put B in communication with the atmosphere, while when the electromagnet (2) is excited the piece of iron B is attracted and the handle of the tap pulled over so as to put B in communication with the water pump.

The electromagnets are in series with a battery, and with connections in the pump, which are so arranged that when the acid rises to a certain level in C the circuit of the electro-magnet (1) is completed, and when the acid sinks below this level the circuit is broken; while when the acid rises to a certain point in G the circuit 2 is completed, while when the acid sinks below the level this circuit is broken. The arrangement shown in the diagram and in the models for making these connections consists of two floats, carrying at their top a conductor which connects two pairs of wires fused into the pump at D and H respectively.



I have much pleasure in thanking Mr. Everett and Mr. Pye, of the Cavendish Laboratory, for the skill they have shown in the construction of these pumps, as well as for many suggestions they have made for the improvement of some of the details.

* Paper read before the British Association in Section A, Nottingham, September, 1893.

The Destruction of Telegraph Insulators.—In connection with a recent case of telegraph insulator destruction, it is worth noting that the amusement of breaking insulators is growing in public favour. In 1887 the number of insulators broken was 11,479; in 1888, 11,802; in 1889, 12,847; and in the first half of 1890, 8,270.

The engines and dynamos are, as usual, in German stations, slow-speed triple expansion, condensing, and direct-coupled machines, each engine running two dynamos, an arrangement which must be disadvantageous, one would suppose, at light loads. The dynamos have the commutator arranged as part of the armature winding, the armature being wheel-shaped, and the brushes running on the periphery, and are, of course, multipolar.

The greatest amount of interest attaches to the scheme of connections, which is broadly as follows:—The current from each dynamo, after passing through fuses, ammeter, automatic cut-out, and indicator to a double-pole two-way switch, by means of which it is led either to the charging contact of the cells or to the corresponding omnibus bar. Eight relays lock the switches for switching in a dynamo, until it reaches the proper voltage. The discharge switches are similarly connected to the five distributing bars, to which the feeders are also coupled. A concrete conduit is used, in which are fixed insulators carried on an iron frame, and so arranged that the conductors are 4in. apart. The copper connections are made by tinning the ends, which overlap about 6in., and inserting two bolts, alteration in length being taken up by S pieces at intervals. Manholes are provided at the feeding points, and the connections are arranged circularly. House connections are made by ordinary armoured cables. The manholes at the feeding points are put so low in the conduit that any water running in must flow into them; and facilities are provided for pumping it out. The conduits are thoroughly ventilated by means of special pipes, and have acted perfectly, in spite of very unfavourable circumstances as regards water, and so on, and no failure of insulation has been reported during nearly three years' working. The conductors are designed for 60,000 lamps at a time, while the present plant can only run 16,000, of which 12,000 by the dynamos alone. The total length of the system is eight miles, and the average distance from the station two-thirds of a mile.

The running of the Königsberg station up to date has shown that the five-wire system is not so complicated in regulation and distribution as has been supposed; on the contrary, its utility has been satisfactorily demonstrated; while the advantages of combining the conduit and five-wire systems are great from the point of view of cheapness and efficiency in putting down the mains.

So much is this the case that, although the mains are laid for more than four times the present number of lamps, the financial results have been throughout perfectly satisfactory.

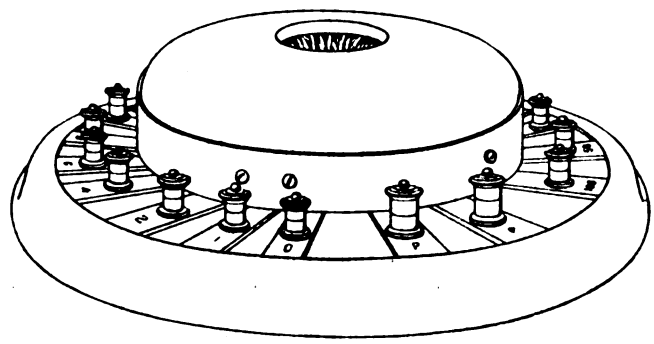
THE ELECTRIC LIGHTING OF CASSEL.*

This work is worthy of notice for more than one reason. The waterfall which is used for the service, while on an average more than sufficient to supply the load, does not suffice for the maximum, and it has therefore been found necessary to store the energy by means of accumulators; while the distance of the source of power from the town has made it necessary to use alternate-current transmission, and direct alternate-current transformation. The falls of the Fulda, at Neumühle, about four miles from the town, are utilised to drive four 50 H.P. turbines, transmitting by bevel gear to the main shafting, which drives by means of gearing two 100 H.P. Kapp-Oerlikon dynamos. An absorption regulator is provided in order to keep the speed constant. Two engines are in reserve in case of accident. The dynamos transmit at 2,200 volts to the two stations in the town, where alternate-current motors, each directly coupled to two direct-current machines, supply the necessary power for the town lighting. These motors are similar in size and construction to the generators, but have no exciters, being excited from the direct-current dynamos. The accumulators run in parallel with the dynamos by means of the usual "charge and discharge" switches, and the remainder of the system calls for no remark. The starting of the motor may be noticed, which is performed in the following manner:—The dynamo is started at Neumühle, and the motor at Cassel, by means of the accumulators, using the direct-current dynamo as a motor. The alternator is then excited, and got into phase in the usual manner, and then switched on. The direct-current dynamos are then coupled to the omnibus bars and the load properly adjusted, the whole proceeding taking only two or three minutes. The efficiency of the system of transmission is 71 per cent., and the total efficiency 55 per cent. The plant has recently had to be increased by addition of more accumulators, and about 10,000 30-watt lamps are now on the mains, and any further increase will necessitate another addition to the plant. The capital expenditure on this work has amounted to about £38 800. The receipts for the nine months, July, 1, 1891, to March 31, 1892, amounted to about £3,500; and the expenditure for works, costs, salaries, &c., was about £1,700; and for interest and depreciation, £1,100; a total of £2,800. The balance added to the amount allowed for depreciation makes about £1,000 towards a sinking fund for repayment of capital. The tariff was from 11d. to 8d. per Board of Trade unit, an average price in Germany, and has been reduced to an average of 9d. The works have been running continuously since July 1, 1891, and were designed by Herr Oscar von Miller.

* Abstracted from the *Elektrotechnische Zeitschrift*, August 4, 1893.

A SUB-DIVIDED TRANSFORMER.

The small sub-divided transformer, illustrated herewith, has been designed by Messrs. Miller and Woods, of 2, Gray's Inn-road, for lighting up lamps of various voltages, or working medical cauteries, &c., from the alternating-current street mains. It is of the ordinary ring type, and has an output of about 300 watts. On 100-volt circuits almost any voltage between 1 volt and 200 volts can be obtained, and on a 50-volt supply anything between 1 and 100 volts. For instance, a lamp of 2 volts can be lit between terminals



Miller and Wood's Sub-divided Transformer.

0 and 2, one of 3 volts between 1 and 4, and one of 70 volts between 30 and 100. For obtaining 101 volts and upward to 200, the primary circuit, or rather the street main, is put in series with the secondary (which can be done owing to their phases being opposed) by means of a piece of fuse wire connected between the primary terminal P and the secondary O. Any portion of the secondary may also be connected so as to oppose the primary. The transformer itself, which is about 5½in. in diameter, is mounted on a piece of slate, and all the connections are on the surface.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 15, 1893.

Business Depression.—The extreme business depression that has existed in the United States for several months seems to have passed the acute stage, but the prospects for an immediate revival are not particularly bright. The electrical industries have stood the strain remarkably well, but some of the weaker firms have succumbed, notwithstanding the consideration to creditors shown by the stronger members in the electrical trades. The General Electric Company has suffered severely in the stock market, one result of which has been great reductions of *personnel* in its elaborately organised departments, and a greater concentration in its manufacturing branches.

The Fort Wayne Electric Company.—One of the important electrical companies absorbed by the Thomson-Houston Company previous to the formation of the General Electric Company was the Fort Wayne Electric Company, which had acquired a very profitable share of the arc lighting business in the United States. A rumour is now afloat that this Company has separated from the General Electric and will hereafter conduct business as a competitor.

The American Institute of Electrical Engineers.—The subject of establishing branches of the Institute in various parts of the United States is being discussed. The argument is that the number of members will be largely increased as well as the number of Papers read. While the former result is considered desirable, many of the members are of the opinion that the increase in Papers would be in quantity rather than in quality, and the proposed measure will therefore meet with much opposition unless the published proceedings of the branches are confined to discussion of Papers read before the main body of the Institute.

Digitized by Google

The Westinghouse Charges.—In the suit of the Westinghouse Electric and Manufacturing Company against the *employés* of the General Electric Company for theft of plans, blue prints, data, &c., the jury failed to agree, and the suit will be re-tried. Almost the entire case of the Westinghouse Company rested on the testimony of the draughtsman who committed the theft; the jury was charged that unless his testimony was corroborated a verdict of guilty could not be returned, and as several witnesses testified to his bad character the result may be attributed to these considerations rather than to the testimony of the defence.

CORRESPONDENCE.

PAPERS FOR THE B.A.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I note your remarks in this week's *Electrician* on the dearth of new matter presented to the British Association at the meeting which has just been held.

As I was not able to be present I cannot judge whether your remarks are justified, though I should say that two of the Papers, at least—Mr. Kapp's and Mr. Snell's—contain information useful to those for whom they were written.

I would seriously ask, however, whether the conditions to which authors of Papers have to submit are such as are calculated to inspire busy men with much enthusiasm for work of this kind. The Section meets at 11 a.m. The writer of the first Paper on the list, usually some eminent man, is sometimes allowed to read his Paper without interruption, sometimes he is not. Speakers on that and all subsequent Papers are repeatedly warned that the time is limited and there are a number of Papers to be read.

Writers of succeeding Papers are asked to condense, and are usually interrupted repeatedly, speakers on them being subject to greater and greater pressure, till at about the fourth Paper—sometimes earlier—the author finds that his audience consists of a certain number of chairs, *plus* a few listeners, while the authors of the fifth, sixth, and seventh Papers are requested to have their Papers taken as read.

It is well known that three hours is as long as any audience can be kept for one subject. Why not let the meetings be for three hours, and accept only the number of Papers that can be read and properly discussed in the time?

If an author, when advised that his Paper will not be likely to come on, elects still to have it put down for reading, no harm is done; but it is surely not far removed from an insult to ask a busy man—and it is the busy men whose Papers are usually of most value—to prepare a Paper to which no one will listen.

If a Paper, too, is to be of value, no matter how eminent or experienced the author may be, surely it is after it has undergone the ordeal of discussion by those who are competent to criticise it in detail.—Yours, &c., SYDNEY F. WALKER.

[Mr. Walker takes the British Association too seriously. He was at great trouble, we remember, with a Paper at Leeds, illustrated by experiments on a large scale. His efforts were sadly wasted. As a lecture before a local scientific society it would have been a great success. This was before Section G, which is quite a holiday gathering.—ED. *E.*]

GLOW-LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If any of your readers will be kind enough to afford me some information on the following points I shall be greatly obliged, and I have no doubt the answers will be of service to others as well as myself.

I suppose it may be taken that the ordinary 100-volt 16-c.p. lamp, when consuming 60 watts, will last about 1,000 to 1,500 hours, say 1,200 hours on the average. What will its life be if run at 105 volts, and is there any proved relation between watts per candle-power and life?

Further, in the case mentioned, will the total watts consumed by the lamp increase in the ratio of 100 to 105, or 63, or will the current increase also, and if so, how much?

Thanking you in anticipation for inserting these queries,—Yours, &c., T. W. WALLIS.

London, September 27, 1893.

[No complete tests of well-known lamps as to the relation between watts and life have been published. The second question is answered in Prof. Ayrton's article on p. 585 of our present issue.—Ed. *E.*]

PATENT RECORD.

A record of Applications for Patents and Patent Specifications Published s compiled for this journal by MR. J. C. CHAPMAN, *Fel. Chartered Inst. Patent Agents, of 70, Chancery-lane, W.C., from whom any information on the subject may be obtained.*

APPLICATIONS FOR PATENTS.

September 11, 1893.

17,025. T. B. SHARP. Birmingham. Improvements in raising and lowering the light of electric glow-lamps.

17,030. G. ST. JOHN DAY and W. H. WHEELER. Manchester. Improvements in apparatus for facilitating the erection or fastening of electrical conductors in wood casings.

17,045. J. H. GASH and J. SKILBECK. London. Improvements in, or relating to, electric clocks, part of such invention being also applicable for other purposes.

17,052. W. J. DAVEY. London. Improvements in arc electric lamps.

September 12, 1893.

17,093. T. SLOPER. Devizes. Improvements in, or relating to, electric telephones.

17,127. T. CRANEY. London. Improvements in electrolytic cells.*

September 13, 1893.

17,172. S. W. BAYNES. Bradford. Improvements in air and water-tight covers for junction boxes used in electrical distribution, and for other purposes.

17,175. T. SLOPER. Devizes. Improvements in, or relating to, electric telephones an dmicrophones.

17,189. J. M. M. MUNRO and J. MCFARLANE. Glasgow. Improvements in electric switches.

17,197. R. E. B. CROMPTON and S. L.'BRUNTON. London. Improvements in dynamo-electric machinery.

17,220. C. A. J. H. SCHRODER and H. E. R. SCHRODER. London. Improved methods of recovering zinc from the waste products of galvanic batteries.*

17,221. C A. J. H. SCHRODER and H. E. R. SCHRODER. London. New or improved galvanic batteries.*

17,234. A. A. GOLDSTON. London. Improvements in electric switches for series circuits.

September 14, 1893.

17,310. SIEMENS BROS. AND CO. (LIMITED). London. Improvements in contact apparatus for receiving currents from overhead conductors on electric railways. (Messrs. Siemens and Halske, Germany.)

17,330. J. W. EDMUNDSON and F. J. SATCHWELL. London. Improvements in holders for incandescent electric lamps.

SPECIFICATIONS PUBLISHED.

All Specifications price 8d. each.

1892.

15,318. LEIGH (Apollonj). Electrical transformers.

15,425. WRIGHT. Burglar detector fire alarm and police call.

15,437. GRAY and PRICE. Electrical contacts.

15,689. WILLOT. Relays for electric telegraphs.

16,315. BOWEN. Electric telegraphs.

16,768. PIPPETTE. Switching telephone, &c., exchanges.

17,092. CROMPTON and DOWSING. Insulating and supporting electric wires.

17,093. AYRTON and MATHER. Electrostatic measuring instruments.

18,357. WYAND and SCHRAMM. Electrical switches.

18,847. JOEL. Field-magnets and armatures of current electromotors, &c.

18,994. TIMMIS. Electromagnets.

1893.

206. SALOMONS and PYKE. Producing light by alternating electric currents.

2,331. EDGERTON. Secondary batteries.

5,987. FLETCHER. Telephone, &c., circuits.

9,262. ERICSSON. Electric meters.

7,848. LEVI. Indicating telegraphic messages.

13,066. BOULT (Stever). Electric incandescent lamps.

13,911. THOMSON (Coffin). Heating, &c., metals electrically.

14,076. LAKE (Armen). Electric measuring instruments.

14,210. SIEMENS BROS. AND CO. (LIMITED). Telegraph posts, &c.

14,474. FORBES. Telephone circuits.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

COMPETITION.—The Morley Corporation announce in our advertisement columns that they are prepared to receive particulars of schemes for the lighting of the town hall and the borough generally. The scheme selected as the most suitable is to be awarded a premium of £100. Conditions of the competition may be obtained on application to Mr. R. Borrough Hopkins, town clerk, and plans and particulars are to be sent in before December 1st.

TENDERS INVITED.—The Royal Company of Portuguese Railways (Lisbon) invite tenders for the installation of the electric light in the Lisbon Station and the Rocio tunnel. Conditions are to be obtained from the Administraca de Companhia real dos caminhos de ferro Portuguezes, Lisbon.

TENDERS ACCEPTED.—The tender of Mr. Willway has been accepted for an electric light installation at St. Peter's Hospital, at Bristol, at £28. 9s. 6d.

——— The Bradford Corporation have accepted the tender of Messrs. Siemens Bros. and Co. (Limited) for the supply of switchboards for their central station.

——— The tender of Messrs. W. Burrow and Son, of Bolton, has been accepted by the Corporation for the erection of the electric lighting station in Spa-road.

APPOINTMENT VACANT.—The Directors of the Scottish House-to-House Electricity Company (Limited) announce in our advertisement columns that they are prepared to receive applications for the post of manager of their new generating station at Coatbridge. Applications to be made by letter only to the Secretary of the Company, 109, Hope-street, Glasgow.

APPOINTMENT.—Mr. T. H. Aldridge has obtained an appointment with the Grand Junction Canal Works at their pumping station at Tring.

DISSOLUTION OF PARTNERSHIP.—Messrs. Newton and Savage, 6 and 7, Tysoe-street, Clerkenwell, E.C., electricians, have dissolved partnership. Debts will be paid by G. C. Savage.

REMOVAL NOTICES.—The Manchester Edison-Swan Company (Limited) notify us that they have removed their offices from 14, St. Ann's-square to Temple-chambers, 29, Brazennose-street, Manchester.——The address of Messrs. Hughes and Lancaster is now Albany Buildings, 47, Victoria-street, Westminster, S.W.

LIQUIDATIONS.—A petition was presented on the 19th inst. by Gen. Sir R. J. Meade for the winding up of Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited), and is down for hearing at the Royal Courts of Justice, Strand, on October 4th.

——— The shareholders of the British Gas Engine and Engineering Company (Limited) have decided to voluntarily wind up the Company, and have appointed Mr. W. S. Mackenzie liquidator.

——— Claims against the estate of the Thorneburry Miners' Safety Lamp Company (Limited) must be sent in to the liquidator, Mr. F. Newton, 9, Warrington-crescent, Maida Vale, by October 21st.

BANKRUPTCY.—A meeting of the creditors of Selina Rowbottom, electrical engineer, of 32, Abbey-street, Derby, carrying on business as S. Rowbottom and Co., was held at Derby last week. The debtor's statement showed liabilities £302. 19s., of which £280. 4s. was expected to rank for dividend. The stock-in-trade, which cost £400, was estimated to realise £250, the machinery £36, trade fittings, &c., £25, furniture £20, and there were good book debts put down at £26. 10s. The alleged cause of failure was bad trade during the past year. The Official Receiver's observations were that the debtor was the wife of Samuel Rowbottom, who was adjudged bankrupt on April 24, 1889, and had not obtained his discharge. His effects were sold by auction, after which Mrs. Rowbottom at once commenced business under the style of "S. Rowbottom and Co.," as she says, without capital. In August last the debtor gave a bill of sale to a creditor, with the result that she was pressed by others, and an execution having been levied on her goods, she filed her petition. It appeared to him that the bill of sale was invalid, and the debtor had so treated it in her statement. The usual resolutions were passed.

ELECTRIC TREATMENT OF SEWAGE.—The Hermite process for the disinfection of sewage by means of electrolysed sea water is, we understand, being tested by Messrs. Merryweather and Sons, of London, with a view to its application to the drainage of seaside towns. The process, which was described in *The Electrician* at the time of its publication, consists in the use of electrolytically-treated sea-water for flushing the sewers.

INCANDESCENT LAMPS.—We learn that the General Electric Company (Limited) have acquired the incandescent electric lamp works built by the Brush Electrical Engineering Company at Brook-green, Hammersmith, for the purpose of manufacturing incandescent lamps. We understand that the plant now installed and being erected is capable of an output of over one million lamps per annum. The management will be in the hands of Mr. C. J. Robertson, well known as one of the most experienced incandescent lamp makers in England and on the Continent.

——— The Brush Electrical Engineering Company announce in our advertisement columns that they will resume the sale of their glow-lamps in the United Kingdom on and after November 10th. The lamps are manufactured at the Company's own works, and are made under the most modern and improved processes.

MESSRS. HARPER'S WORKS, ABERDEEN.—We are requested to state that the electric installation at these works was designed and constructed by the General Electric Power and Traction Company (Limited), Kentish Town, London.

PORTABLE BATTERIES.—The Edison and Swan United Electric Light Company have issued an illustrated price list of portable secondary batteries of various sizes. Resistance lamps for charging are offered, and full directions for use are given.

ABERYSTWITH.—The Town Council at their meeting last week adopted a recommendation of a committee meeting of the whole of the Council to transfer the powers, &c., obtained under their Provisional Order, to a company or person, with the approval of the Board of Trade, and not to carry out the order themselves. A further recommendation that the order be transferred to the Bourne and Grant Electricity Supply Company (Limited) was discussed, but a decision was deferred until an interview had been held with Messrs. Bourne and Grant, a special meeting of the committee being called for that purpose.

BRUSSELS.—The electric light is to be experimented with on the local railway. It is said that the Schmid type of lamp is to be employed.

CARDIFF.—A complaint was made at a meeting of the Cardiff Lighting and Electrical Committee held last week of the defective lighting of a number of the principal streets by the gas company. The light inspector stated that he had brought the matter before the notice of the company several times, but nothing beneficial had resulted, and it was ultimately resolved that the gas company be communicated with on the subject, and that the sub-committee consider their position with regard to the agreement with the gas company in the matter.

CHAPEL LIGHTING.—The Bayswater Wesleyan Chapel is the first chapel in London belonging to that body which has adopted the electric light. An installation, comprising 73 incandescent lamps, the majority of them 16 c.p., has been carried out by Messrs. Money and Nash, at a cost of £125.

CHIPPENHAM.—The extensive premises of the Wiltshire Bacon Curing Company are lighted throughout by electricity, and the 250-light dynamo being larger than is required by the Company, it has been suggested that, with a small additional outlay, increased power could be procured sufficient to light the town and for private purposes. Some experiments in this direction have been made and have given satisfaction; and it is thought that an arrangement may probably be come to between the Corporation and the Bacon Curing Company for the supply of the current at a reasonable rate.

CITY OF LONDON UNION.—The City of London Board of Guardians have referred to the House Committee to consider and report as to the desirability of lighting the Infirmary at Bow by electricity.

CLERKENWELL.—Mr. Sidney Morse has made another application to the Vestry for an extension of time in which to complete the electric light installation. The Vestry have previously declined to grant the extension, and at their last meeting resolved that they could see no reason at present for altering their decision.

DERBY.—Rapid progress is being made with the Corporation's scheme of street and private lighting by electricity in this town, and the arrangements for the latter are almost completed. There will be two circuits in each street, and every alternate lamp will be placed on one of these circuits so that one half of them can be lighted or extinguished simultaneously. By a switch placed in the pillar each lamp can be extinguished separately. The city is divided into two sections (east and west), and each district has its own distinct and separate circuits and generating machinery. All the city south-east of Shipquay-street and Bishop-street, including the Waterside, will be supplied through its own distinct duplicate circuits from two Siemens constant-current dynamos, and all the city north-west of these streets will be supplied by different circuits from another pair of dynamos. A third or spare set of dynamos are in the station as a stand-by, to be switched on to any circuit in case of accident. These six dynamos are each capable of

Digitized by Google

running 60 arc lamps of 2,000 candle-power each, but as two of these will be held in reserve there will be in constant use four capable of running 240 efficiently. The present contract is for 160 lamps The arc lamps are of the Brockie-Pell type. The conductors are armoured and laid directly in the ground. It is estimated that the annual payment now made to the gas company for street lighting will cover the repayments and interest of the loan of £15,000 obtained by the Corporation, and it is estimated that after the loan is paid off the cost of lighting the city by electricity will be only one-third of the cost of lighting it by gas. The generating station has been erected, the boilers are set, the machinery is in course of erection, and Messrs. Siemens Brothers and Co. are engaged laying the underground cables and wiring the lamp pillars, and by the end of next month it is expected that two of the circuits will be lighted, and the other two circuits immediately after; so that all the installation will be completed and working this winter. The Corporation is said to be ready at any moment to undertake the private lighting, provided a sufficient number of the ratepayers intimate their wish to be supplied.

ELECTRIC LIGHTING IN EDINBURGH.—Prof. Kennedy, London, in a report to the Electric Lighting Committee of Edinburgh Town Council, advises that the whole business part of the city, from the Register House to Donaldson's Hospital, and the principal streets and terraces, along with part of the South Side, including Cockburn-street and part of High-street, should be lit. In considering the system to be adopted he has selected two for recommendation, namely, the three-wire system similar to that he has used in Glasgow, and a combined high and low-tension system such as that used by the City of London Company. The total cost in each case, including an allowance of £10,000 for buildings, and including also the arc lighting plant, but not including the cost of land, would be about £80,000. The cost of doubling the capacity of the plant and mains, when this should become necessary, would be about £30,000 in the first case, and about £28,000 in the other. There was thus no practical difference in capital cost between the two systems, and so far as expense went the decision as to which was best in this case must depend on the cost of working them. The working costs for a three-wire system were well known, as many were in operation. The cost of working a combined high and low-tension system could hardly yet be said to be known, as no system of this kind had been at work anywhere for a sufficient length of time. It had, unavoidably, the considerable additional annual expense of the rents of the transformer sub-stations, and the wages of the men employed to attend to them; and including this the lowest estimate which he could make of the difference in cost of production between the two systems was 0·5d. per unit on 680,000 units per annum (the difference might well be much greater). The balance of advantages, therefore, seemed to him very much in favour of the use of a three-wire system for the northern district, and he recommended the adoption of this system. He also recommends a charge of 6d. per unit.

FALMOUTH.—The Town Council have adopted the recommendation of the Lighting Committee to accept the offer of Messrs. Veale and Co. (Limited) to report on the electric lighting of the main streets for the sum of £8.

GOVAN.—At a meeting of the Govan Lunacy Board last week it was reported that to light Hawkhead Asylum by electricity would cost £5,300, and that the yearly working charges would be £269. 5s. No decision, however, has yet been come to respecting the best mode of lighting the building.

HUDDERSFIELD.—The whole of the rooms on the ground-floor of the Technical School have been fitted up with the electric light and on Tuesday week the supply of electricity from the Corporation mains was formally turned on. It is contemplated to extend the installation to the whole of the school.——The Town Council at their last meeting confirmed minutes of the Electric Light Committee recommending the payment of £3,000 on account to the Brush Electrical Engineering Company; that six 18-kilowatt transformers be purchased for the town hall and the sub-stations, at an estimated cost of £56 each; that nine 1,500, nine 3,000, and six 6,000 transformers be purchased from the Electric Construction Company at an estimated cost of £400; and that eighteen switchboards for transformer stations be obtained, at a cost of £7. 5s. 6d. each.

HULL.—At a meeting of the Committee of the Hull Guardian Society held last week, the Corporation's electric light supply came under discussion, and it was stated by several members of the Committee that, in their opinion, there would be a greater demand for the light if the charges were reduced.

KILLARNEY.—At the last meeting of the Board of Governors of the Killarney District Lunatic Asylum a letter was read from the Board of Control, Dublin, stating that the Board of Control had given the matter of the introduction of the electric light into the asylum careful consideration, but they were not at present advised or prepared to sanction the scheme proposed. Some discussion followed the reading of the letter, and the Board of Governors eventually resolved to ask the Board of Control on what grounds the scheme had been rejected by them, as the Board of Governors had on several occasions fully discussed the subject before adopting it.

KINGSWOOD.—Some discussion arose at the meeting of the Local Board last week as to the electric lighting of the district. Complaint was made that the lights were very bad, and the Clerk said that the fault lay with the lamps, but new ones would shortly be introduced.

LEICESTER.—The Town Council have directed the Gas Committee to at once proceed with the arrangements necessary for carrying out the electric lighting scheme adopted by the Council.

LEWISHAM.—The Crystal Palace District Electric Supply Company have forwarded to the Lewisham District Board of Works a list of roads in which their mains are laid, and have inquired whether the Board were prepared to entertain proposals for lighting by electricity the whole or any part of it. The question has been referred to the Works Committee.

MELBOURNE.—In reply to questions, Mr. Alderman C. J. Ham said at the quarterly meeting of the Town Council on August 10th that the sum originally estimated for the lighting of the city was £75,000, but there was also a sum of £125,000 appropriated for electric lighting works out of the loan of 1892. The electric lighting committee judiciously decided to proceed one step at a time, and carry out the system of public lighting first. As far as he could ascertain, the actual cost would not be in excess of the estimates, and the lighting of the public streets would be effected at a cost within £75,000. The sum of £125,000 appropriated was, he said, not available. Councillor Carter remarked that the Corporation evidently intended to spend the ratepayers' money in competing with existing lighting companies. By such competition the Corporation could bring about the ruin of those companies. Surely, he thought, the Corporation should first of all either buy up the companies or deal with them fairly. The Mayor ruled that these remarks had no bearing on the order of the day. He would point out, however, that the subject of private lighting would come up for discussion after the public lighting had been dealt with. The order of the day was adopted.

MONMOUTH.—A special meeting of the Town Council was held on Friday, when a scheme comprising a complete system of drainage, together with the introduction of the electric light for streets and private dwellings, was adopted. The engineer is Mr. C. Nicholson Lailey, of Westminster, and the cost will be about £16,000.

PENRITH.—At the last meeting of the Board of Health a resolution was passed "That the clerk be instructed to take steps to procure a Provisional Order to enable the Board to provide an electric light installation for Penrith."

PETERBOROUGH.—Mr. J. C. Gill, the borough engineer, has prepared a report upon the question of electric lighting for the city. It is proposed to light the central portion of the town, the mains to be extended as required. Mr. Gill estimates the total cost of buildings, engines, dynamos, accumulators, mains, switchboards, and instruments required for making the Peterborough installation complete at £12,500. To earn 5 per cent. per annum upon this capital, and to provide for working expenses, an annual revenue of £1,710 would be required; and Mr. Gill concludes, from inquiries which he has made, that in a few years the works proposed would be earning sufficient profits to be a valuable property.

RUGBY.—During the vacation the Rugby School Electric Lighting Company (Limited) have been engaged in fitting up for electric lighting the different boarding-houses, the school-house, and the whole of the school buildings, with the exception of the art museum and the school chapel. The dynamos will be driven by a 40-H.P. gas-engine, using Dowson's gas. The work has been entrusted to different contractors, and will be completed before the school re-opens. The whole of it has been done under the general supervision of Mr. J. A. McMullen. The installation will embrace upwards of 1,500 lights, Ediswan incandescent lamps being used. The Company is being carried on on the co-operative principle, all the subscribers being consumers and Directors of the Company.

RYDE.—The Electric Lighting Committee have recommended that the Council apply for a Provisional Order enabling them to supply electric light in their district, and that they obtain powers to borrow the necessary amount.

SOUTHAMPTON.—The electric cranes on the Town Quay formed the subject of a short discussion at the meeting of the Town Council last week. The Works Committee reported that Messrs. Statter and Co. had offered to supply some spare parts of the cranes at a cost of about £150, but that they had not entertained the offer, as they expected that both cranes would be at work shortly with every requisite appliance provided, although permission had been given the firm to make some tests as to the efficiency of the cranes, on the understanding that they paid for the current supplied. The Sheriff said he thought it would be

Digitized by Google

understood that they were not yet taking over the electric crane, and would not do so until they were satisfied that it was competent to do the work which was expected of it according to the conditions and requirements of the contract. It did, he understood, lift about one-third of the weight it was supposed to lift and worked with that weight fairly well; but he hoped the Committee would not see fit to make themselves responsible for the payment for this crane until it was rendered capable of doing what it was expected to do. Alderman Bone, the Chairman of the Works Committee, replied that the cranes had not yet been tested, but would be in due course; and he felt sure that they would be found capable of doing the work they were supposed to do. The Committee's report was then adopted.

WAKEFIELD.—Mr. Robert Hammond has been engaged as Consulting engineer by the Corporation to prepare plans and advise the Town Clerk as to the Provisional Order which it has been resolved to apply for.

WANDSWORTH.—Mr. Sidney Morse having applied to the District Board of Works for an extension of time for complying with Section 7 of the Provisional Order granted to the County of London Electric Lighting Company, the Board have agreed to an extension of six months.

WEST CALDER.—The premises of the local Co-operative Society have been lighted by electricity for the past four years, and the plant has now been enlarged so as to form a central station for the distribution of the light throughout the district. The current was switched on on Friday last to the different circuits throughout the village.

WESTON-SUPER-MARE.—The Brush Electrical Engineering Company have supplied the Town Commissioners with an estimate of the cost of supplying the district with the electric light, but the Commissioners have decided to refer the whole question of electric lighting to a sub-committee.

WREXHAM.—On Wednesday last week a special meeting of the Town Council was held for the purpose of considering in committee a letter from Messrs. Lewis and Son, solicitors, stating that the Wrexham and District Electric Supply Company (Limited) were prepared, in accordance with the offer made by the Chairman of the Company to the Lighting Committee on April 25th, to sell to the Corporation the Provisional Order of the Company for the sum of £500. Considerable discussion took place, and it was generally held to be unwise to expend £500 on a Provisional Order which had only a year to run. The Town Clerk said that the Corporation would be able to obtain an Order for about £250, and it was eventually resolved to offer the Company this sum for their Order.

YEADON.—At a meeting of the Local Board last week a letter was read from M. Robert Hammond giving the terms on which he would prepare a scheme for the lighting of the district. The Board decided to have a further interview with Messrs. Andrews and Preece, and then to call a public meeting for the purpose of asking the ratepayers' sanction to the Board undertaking the supply of electricity for both public and private lighting.

COMPANIES' MEETINGS AND REPORTS.

Halifax and Bermudas Cable Company (Limited).

As briefly reported in last week's issue, the fourth annual general meeting of this Company was held at the offices, 33, Old Broad-street, London, E.C., on Wednesday, September 20th, when the Directors' Report (as follows) and Statements of Accounts were unanimously adopted:—

The Directors beg to submit to the Shareholders duly audited Statements of Accounts for the year ending June 30, 1893. The result of the working is a profit of £1,717. 8s. 5d., as compared with £1,261. 14s. 2d. for 1891-92. To this has to be added the balance of £1,681. 19s. 7d. brought forward from last year, making the sum to the credit of revenue £3,399. 8s. 0d. The net cable receipts in the past year were £4,856. 14s. 8d., as compared with £3,915. 13s. 3d. in the preceding year. This increase is chiefly due to a greater number of vessels calling at Bermuda for orders and to refit. The growth of this business is very advantageous to Bermuda, and it is the direct result of the establishment of cable communication. Other sources of traffic have been maintained.

The Company's cable has throughout the year worked with complete efficiency, and its electrical condition is excellent.

The Directors have during the year continued to give their attention to the one or two outstanding matters of an unsatisfactory character, due to the early experience of the Company. The loan of £9,000 had of the Gresham Life Office at 6 per cent. has, since June 30th, been still further reduced to £6,800, and the rate of interest to 5 per cent. Further, the £10,153. 16s. 10d. which appeared in the last balance-sheet as debit against capital account has been reduced to £6,754. 8s. 10d. by the application of the £3,399. 8s. to credit of revenue account.

The fund for the redemption of the debentures is now £7,995 6s. 2d., as compared with £5,175. 16s. 9d. last year.

Under the Articles of Association Mr. T. G. H. Glynn and Mr. Thomas Skinner retire on this occasion, and offer themselves for re-election. The Auditors, Messrs. Gribbon, Ingram, and Holroyd, also retire, and offer themselves for re-election.

NEW COMPANIES, STATUTORY RETURNS, &c.

[*In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1893, pages 320-348, *&c., &c.*]

FARADAY ELECTRICAL ENGINEERING COMPANY (LIMITED).—This Company has been registered in Edinburgh with a capital of £1,600, divided into 4,600 shares of £1 each, to acquire and carry on in all its branches the business of electrical engineering as lately carried on by William M'Whirter at the "Faraday" Electrical Engineering Works, Campbell-street, Govan. The first subscribers (with one share each) are:—James Johnstone, Patrick R. Macdonald, John Macdonald, Peter Galbraith, A. H. Johnstone, Alfred Johnstone, and J. Lumsden Oatts. The first Directors are:—Peter Galbraith, James Johnstone, and John Macdonald, all of Glasgow.

JOHN FORSTER AND CO. (LIMITED).—This Company has been registered, with a capital of £5,000, in £1 shares, to carry on business as mechanical engineers, machine and engineering tool makers, boiler makers, iron and brass founders, metal workers, &c.

GLOBE TELEGRAPH AND TRUST COMPANY (LIMITED).—The annual return of this Company, made up to August 10th, has been filed. The nominal capital is £500,000, divided into 250,000 Preference and 250,000 Ordinary shares of £10 each. 180,042 Preference and 180,227 Ordinary shares have been taken up, the full amount called, and £3,602,690 paid in respect thereof.

LAING, WHARTON, AND DOWN CONSTRUCTION SYNDICATE (LIMITED). The annual return of this Company, made up to August 11th, has been filed. Out of a nominal capital of £100,000, in £10 shares, 4,516 have been taken up, and 1,130 of these have been issued as fully paid. Upon 2,260 the full amount has been called, on 329 a call of £5 per share has been made, and on £397 £2. 10s. per share has been called, resulting in a total payment of £29,237. 10s. During the past financial year 2:0 of the shares issued as fully paid have been returned and the certificates cancelled.

MIDLAND HOUSE-TO-HOUSE ELECTRICITY COMPANY (LIMITED).—The annual return of this Company for 1893 shows that only the seven Subscribers' shares and the 100 Founders' shares issued as fully paid to the parent Company have been taken up. No payments have been made.

ORIENTAL TELEPHONE AND ELECTRIC COMPANY (LIMITED)—The annual return of this Company, made up to September 6th, has been filed. The nominal capital is £300,000, divided into 225,000 Ordinary and 75,000 vendors, and 223,746 of the former, and all of the latter have been taken up. The Vendors' and 3,746 Ordinary shares have been allotted as fully paid. Upon the remaining 220,000 Ordinary shares a call of 11s. per share has been made, resulting in a payment of £121,000.

WATERHOUSE ELECTRICAL MANUFACTURING COMPANY (LIMITED). The statutory return of this Company, made up to May 24th, has recently been filed. The nominal capital is £20,000, divided into 1,000 Vendors' and 1,000 Ordinary shares of £10 each. All the former and 272 of the latter have been subscribed for and allotted, the former being issued as fully paid to Messrs. Addison G. Waterhouse, Frank G. Waterhouse, James N. Gamble, Francis T. Chambers, and Reginald Bolton. Upon the Ordinary shares a call of £6. 13s. 4d. per share has been made, resulting in the payment of £2,563. 6s. 8d. (which includes a sum of £2,250 paid in respect of 225 shares), leaving £156. 13s. 4d. in arrears.

CITY NOTES, &c.

ANGLO-AMERICAN TELEGRAPH COMPANY (LIMITED).—At a meeting of the Board of Directors of this Company on Friday, it was resolved to declare an interim dividend for the quarter ending September 30, 1893, of 12s. 6d. per cent. on the Ordinary stock and 25s. per cent. on the Preferred stock, less income-tax, payable on November 1st to the stockholders registered on the books of the Company on September 30, 1893.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended September 24th were £773, as against £768 for the corresponding period of last year, being an increase of £5. The total receipts for the half-year amount to £9,653, against £9,208 in the corresponding period of 1892, being an increase of £445.

EDISON ELECTRIC ILLUMINATING COMPANY OF NEW YORK.—The net earnings of this Company in the first half of this year amounted to $282,302, as compared with $225,566 in the corresponding period of 1892, and $152,301 in the corresponding period of 1891. The number of incandescent lamps in operation at the close of June, 1893, was 75,524, as compared with 56,704 at the close of June, 1892, and 50,615 at the close of June, 1891. The number of arc lamps in operation at the close of June, 1893, was 2,008, as compared with 1,153 at the close of June, 1892, and 313 at the close of June, 1891.

EVERED AND CO. (LIMITED).—The Directors have declared an interim dividend at the rate of 7½ per cent. per annum for the half-year ending June 30th last.

SOCIETE GENERALE DES TELEPHONES.—It is announced that the scheme for the reconstruction of this Company has now been completed, and will shortly be laid before the shareholders for their approval.

STOCK EXCHANGE NOTICES.—The Stock Exchange Committee have appointed to-day (Friday) a special settling day in the further issue of £50,000 Five per Cent. Debentures, Nos. 5,001 to 10,000, of the Metro-

Digitized by Google

politan Electric Supply Company (Limited); and have ordered these securities and the further issue of 15,000 Preference shares, Nos. 75,001 to 90,000, and 12,022 Ordinary shares, Nos. 77,979 to 90,0 0, of the Brush Electrical Engineering Company (Limited), to be quoted in the Official List.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended September 22, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,223.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 803.—Vol. XXXI. FRIDAY, OCTOBER 6, 1893. PRICE FOURPENCE. *Annual Subscription (U.K.), 19/6*

NOTES.

By the death of Sir Arthur Blackwood the Post Office suffers a bereavement far more serious than would be occasioned by the mere loss of a valuable and popular chief. During the twenty years that he held high office Sir Arthur was foremost in every movement for the advancement of the service and the well-being of its employés. Dominated by a strong religious personality, he has exerted, notably on the rank and file, an influence which will be more enduring probably than his fame as an administrator. Popular in every branch of the service, he was best known, perhaps, in the telegraph section; and the good work done among the messenger boys, under his never-tiring guidance, has achieved wonders in raising the moral tone and physical welfare of the rising generation of postal and telegraph servants, whose ranks are recruited from that body.

The letter from Dr. Lodge in our correspondence columns this week, referring to the Sectional work of the British Association, is very much to the point. The value of this Association to Science arises, we think, from three causes. In the first place, a number of most valuable reports have been presented from time to time, which have been carefully prepared by the greatest authorities on the subjects of which they treat. They at once take the standing of classical work, and are frequently referred to in after years. Then, again, there is all the work which has been done in connection with the determination of the electrical standards. This work has from the first been a speciality of the British Association, and its great importance is universally felt, but is, in a sense, accidental, since it is generally supposed that one of the main objects of the Association is to popularise science. The holiday nature of the gathering attracts the attention of the outside public, and, perhaps, if the holiday spirit were more apparent in the meetings than is at present the case the success of the Association would be greater than it is.

We agree with Dr. Lodge that serious Papers are not much wanted at these gatherings, and if this were more generally recognised, such complaints as that of Mr. Walker in our last issue would not be made. The outside public go to hear and see celebrated scientific men. This is also partly the object of many of the members themselves; but to them the chief value of the meetings lies in the reception of new ideas, and these are more likely to be imparted in an informal discussion in which many take part, than in the reading of a number of Papers, to the exclusion of discussion. We have ourselves little doubt as to the existence of a feeling of dissatisfaction among many of those who attend the meetings of the British Association, although no one, as far as we know, has imparted any blame to those who are responsible for the manner in which these meetings are conducted.

The common complaint that the Sectional committees mainly consist of cliques appears to be due to the erroneous idea that the reading of Papers is the primary work of the Sections. This idea is encouraged by the reticence of the committees as to the titles of the Papers which have been received or definitely promised, and the fact that all outsiders are kept in ignorance of the programme for any day until nine o'clock on the morning of that day, while members of the committee are acquainted with it about sixteen hours previously. They can easily settle their plans for the morrow, while outsiders, fearing lest they may miss something important, can make no plans until they see a copy of the programme at the reception room or in some enterprising local newspaper. The committee becomes a clique rather perforce than by intention, and if our estimate of the general opinion of outsiders is correct, there is no other cause for dissatisfaction worth mentioning. "Friendly and mutually helpful impromptu discussion" has always been the most attractive feature, especially of Section A, but to rely on impromptu discussions would be unwise in any association with less zeal than the Society of Friends. Dr. Lodge, however, appeals not to us but to our readers, and we readily invite the discussion which he suggests.

The effect of the presence in an electrolyte of more than the conventional number of conductors serving as electrodes, seems to be in process of becoming a favourite object of study among physicists, for following on the investigations of Dr. Oettel to which we have recently devoted some space, comes notice of a Paper by Mr. John Daniel, entitled "Polarisation, Using a Thin Metal Partition in a Voltameter," dealing with a different aspect of the same or a similar phenomenon. The behaviour of a metallic diaphragm interposed between anode and cathode so that communication from one to the other must take place through the partition, varies with the nature

Digitized by Google

of the partition, with that of the electrolyte and with the current density. In general, gas is evolved at the surface of the partition when its thickness exceeds a certain limit, while no sign of activity occurs when the limit is not reached. A natural corollary of this is that very thin diaphragms escape the oxidising effect of the products of electrolysis, while those that are thicker are attacked even to destruction. The observation suggests many interesting speculations, but from these we refrain until a few preliminaries are settled. In the first place, it is necessary to be certain that the partition constitutes an absolute mechanical means of separation. Then, moreover, proof of the absence of molar spaces in the partition itself is requisite. All who have held a piece of tin-foil up to the light will know what a riddle an apparently continuous metal sheet may be, and will scarcely undertake the solution of a problem containing an unknown number of unknowns. We await the publication of the complete Paper with much interest.

A Paper read by Dr. Bodländer at the recent congress of the German Society which corresponds pretty closely with the British Association, deals with the vexed question of the subsidence of finely divided matter in suspension in liquids, and endeavours to explain it by appeal to the magic term electrolysis, which is fast ousting polarisation from the position of consoler to the perplexed electrician who clings to elegant periphrasis when elucidation is not forthcoming. The author of the Paper finds that the clarification of a turbid liquid is promoted by the addition of substances which are electrolytes, such as acids, bases and salts, while bodies of the class of alcohol and sugar have no such influence. It may be remarked in passing that this is scarcely consonant with ordinary analytical experience in dealing with argillaceous materials, which remain obstinately in suspension in alkaline solutions although promptly precipitated when an acid is present. This may, however, depend on the fact also observed by Dr. Bodländer, that the clarifying effect is not perceptible below a certain limit of dilution. The vigour of the action of the alien substance inducing precipitation, increases with its conductivity, leading to the hypothesis that the effect of the electrical charge possessed by each ion of a dissociated electrolyte, may be analogous to that of the discharge from the poles of an influence machine in a dusty atmosphere which causes the agglomeration of the finely divided particles. Whatever the *vera causa*, it is certain that many substances when suspended in water free from electrolytes pass into a state of subdivision so fine as to be indistinguishable from the solution of a colloid and precipitable by the addition of an electrolyte. A practical deduction is that calcium chloride and magnesium chloride, both cheap salts, can be advantageously used for the clarification of turbid waste waters from manufacturing processes. The formation of a delta, on contact of a turbid river water with the saline sea, might to some extent be ascribed to the same action.

Had proper care been exercised in arranging the details of the tug-of-war which recently took place at Chicago between a steam locomotive and the 30-ton electric locomotive, described in *The Electrician* of July 28th, page 344, there is no doubt that much greater importance might have been attached to the results. The nominally 30-ton locomotive, which, however, weighed but 27 tons, was pitted against a small steam locomotive having a weight of 28½ tons on the driving wheels, or 1½ tons in excess of its opponent. Thus much was in favour of the steam locomotive, though with other conditions equal it could not have told much in favour of the heavier engine. On the other hand, the electric locomotive had a very decided advantage from the fact that its most powerful effort occurs under statical conditions, and is very much more in excess of its running effort than is the statical effort of a steam locomotive as compared with its running effort; assuming, of course, that there is a normal pressure on the mains of the one, and a normal pressure in the boiler of the other. As far, then, as the mere useless experiment is concerned of statically pitting a steam locomotive against an electric locomotive of equal weight, we have every reason for predicting the "triumph" of the latter.

But there are two obvious criticisms upon the tests made at Chicago. In the first place, the tests are absolutely unreliable and useless, because, if we are correctly informed, the level of the drawbar was not parallel with the rails, but was tilted in a manner to cause the trailing wheels of the electric locomotive to lose their grip of the rails, thus throwing the burden upon one motor alone. In the second place, such a trial as this, even if carried out under conditions which would make the comparison a fair one, can give but little indication of the true relative merits of the several engines. Even granted that, statically, the electric locomotive is the superior, it will by no means necessarily follow that it will draw a greater load of coaches at any really useful speed than its steam rival. In fact, it might be safely predicted that of two locomotives of ordinary design, the one steam and the other electrical, having equal weights and giving an equal statical effort on the drawbar, the former would be found capable of drawing the greater load at any given speed. It is therefore not on these, but on totally different grounds of comparison that the electric locomotive can either claim or be expected to acquire any useful ascendency over the steam locomotive.

The Paper by Prof. Carhart on "Arc Lamps," which was read before the Chicago Congress, is printed in our present issue, because the curves which accompany it contribute some information, although the observations, as in most photometric tests of arc lamps, are very irregular. We must, however, call attention to the fact that these results cannot be considered as representative of good arc lamps. We know nothing of the quality of the carbons of the Standard Carbon Company, of Cleveland; but we cannot attribute the very poor result to bad carbons. The most obvious reason for so low a candle-power seems to be the use of carbons of the same diameter for both positive and negative. This common practice has no excuse when cored carbons are used for positives and plain carbons

Digitized by Google

for negatives. In the old days of 11mm. carbons for top and bottom nobody cared about watts per candle-power or for sputtering and fireworks.

Since the exhaustive and trustworthy tests of glow lamps at the Franklin Institute, in conjunction with the Philadelphia Exhibition some years ago, no systematic and complete set of lamp tests has anywhere been made. The Philadelphia tests were, for some time after their publication, a mass of reliable information on the life, efficiency and candle-power of glow lamps. But time has worked such changes, both in the mode of manufacture of the lamps themselves and in the practical conditions under which they are worked, that it is necessary to look around for a mass of fresh data which shall take the place of the older information. We look around in vain. With the exception of the disconnected and incomplete researches—valuable as far as they go, but telling us really nothing final—of some experimenters in this country and in Germany, there is no material at our disposal. In another column we print an abstract of the arrangements which have been made for some glow-lamp tests at Chicago. Our readers may judge for themselves whether much commercial or practical value can be attached to lamp tests which, arranged to commence on September 8th, will be continued only (Sundays not included) till the end of October. The maximum time under which a lamp can be tested will be about 1,130 hours; and, these being without any intermission other than the Sunday hours, it is evident the conditions imposed on the lamps cannot fairly be considered to resemble those of actual practice. Life tests of this sort, and with the arrangements for maintaining a perfectly steady pressure which have been adopted, can have nothing but a fanciful and fictitious significance, and will be no guide to either the engineer or the consumer as to the relative merits of the lamps when at work on ordinary lighting mains. It is quite time the solid work of the Franklin Institute tests was repeated upon modern lamps.

Erratum.—In the article on "New Lamps for Old" in our last week's issue the expression "lamp hours" was inadvertently used in one or two cases for "candle hours." In all cases "candle hours" were intended, and the expression "lamp hours" should not have been employed anywere in the article.

Electric Traction for the St. Clair Tunnel.—The St. Clair Tunnel Company are still considering the advisability of adopting electric traction on the trains running through the tunnel, and have now got as far as to obtain estimates from the Canadian General Electric Company for an electric equipment.

Very Curious.—A daily newspaper across the Atlantic thinks it is "a curious anomaly that at the very time that the application of electricity to all the purposes of civilisation has shown such an extraordinary development the demand for steam-engines has increased in almost the same proportion." It is equally curious that the demand for flour has increased in proportion to the demand for bread.

Electric Motors in Factories.—A twelvemonth ago we described the 500 H.P. dynamo at Herstal which generates current for driving the Small Arms Factory, the whole of the machinery being thus driven. Early this year another large dynamo was set to work, coupled direct not to a Corliss engine as in the former plant, but to a 300 H.P. compound Willans central valve condensing engine, running at 350 revolutions per minute.

Shovelling the "Elastic Solid."—Prof. Lodge, says the *Journal of Gas Lighting*, talked about the ether at Nottingham, and he was listened to respectfully. But the question at issue was left exactly where it stood before he opened his mouth. We do not wish to write disrespectfully of the undulatory forces, remarks our contemporary, but it would be an immense relief to the mind if someone could only succeed in getting at the ether with a shovel!

Memorial Willans Fund.—We are asked to mention that the subscription lists for this fund will be closed on November 1st, so that any engineers or others who intend to send in subscriptions, and have not done so, should do so at once. Mr. Alexander Siemens, 12, Queen Anne's-gate, Westminster, is the treasurer of the committee. It may be remembered that the proposal is to establish a fund in connection with the Institution of Mechanical and Electrical Engineers, from the interest of which a premium might be awarded for Papers relating to the subjects which the late Mr. Willans made so peculiarly his own.

Japanese Coal.—Japanese coal (the Vice-Consul at Nagasaki, Japan, reports) is becoming one of the most important articles of the foreign trade of that country. It is, he says, competing with advantage in the way of better market, more rapid production, and less waste with the coal supplied from England and Australia to the markets of China and Singapore. This applies specially to the requirements of navigation, railways, and steam. The coal mines of Japan have reached the total yield of 3,000,000 tons per annum. Japanese coal is stated to be in favour at foreign markets, and its consumption in its own country is also on the increase. An analysis of the Japanese coal gives the following result:—Carbon, 79·26; hydrogen, 5·86; oxygen, 8·76; sulphur, 0·11; ashes, 4·56; water, 1·50. It will be seen that this fuel is more bituminous, and has a higher evaporative power than the average English steam coal.

Mathematical Signs.—In France and Germany one-fourth ($\frac{1}{4}$) reduced to a decimal is written as 0,25; in England it is written 0·25 (always with the period at the top of the line), and in the United States in this way, 0.25. Sir Isaac Newton is given the credit of originating the English method of using the decimal point, his reason being that by placing it at the top of the line it could be distinguished at a glance from the "full stop" punctuation mark. All English mathematicians use the mark in the way proposed by Newton, and the period as a sign of multiplication. It is satisfactory to note that the French show signs of conversion to the English method of marking the decimal place. For instance, in a recently published electrical pocket book the author, in a table of squares, cubes, and reciprocals, calls attention to the fact that "la virgule est remplacée par le point relevé," but in all other tables the, to us, confusing comma has been left in. In subsequent editions it is to be hoped that this reform will no longer make a full stop at the table of squares.

The Measurement of Self-Induction.—In a recent number of *La Lumière Electrique*, M. Blondel discusses the various methods of measuring the self-induction of an electric circuit, the magnetic circuit through which possesses variable permeability. M. Blondel rightly points out that on strictly logical grounds the expression "coefficient of self-induction" is not applicable to this case of inductance, as the inductive effects are functions of the degree of magnetic induction. But he adds that in certain investigations it is convenient to introduce into the expression for the electromotive force due to self-induction, one or the other of two analogues of the usual coefficient. The first of these is the differential coefficient of the magnetic flux with respect to change of current; the second is the ratio of the total magnetic flux to the total current producing it. The former, of course, gives the instantaneous value of the self-induction; the latter represents its integral between limits of zero and the magnetic induction at the instant. In the latter part of his Paper, M. Blondel discusses the application of these two functions and the modes of measuring them.

St. Petersburg.—The one hundredth anniversary of Faraday's birthday was celebrated in a not inappropriate manner at St. Petersburg, on September 10, 1891, by laying the foundation stone of the electric light station at the Imperial Medical Academy. Exactly one year later the first electric light supplied by this station was run, probably an intentional "coincidence." Whether anything extraordinary happened at this station on September 10th of this present year we cannot say, but during the last twelve months considerable progress has been made. The whole area, says *Engineering*, is about one square mile, and the system chosen was high pressure, alternating current, with transformers. The station is situated on the Neva, to facilitate the supply of water and coal. The following losses in the cables were allowed for:—In the primary and secondary cables 2 per cent., in the dynamos and transformers 8 per cent., giving a total drop of 12 per cent. The engines are vertical triple-expansion engines, each of about 350 H.P. indicated. Two of these are now at work, and a third is being erected. These engines are direct-coupled to large Ganz alternators, capable of an output of 200 kilowatts at 2,000 volts. The leads outside the station are of bare silicium bronze wire, protected over steel crossings by steel bearer wires. Oil insulators are used. According to some recent tests, the consumption of coal and water per indicated horse-power hour is 1·54lb. and 13·4lb. respectively, but the more useful tests of the consumption per electrical horse-power hour do not appear to be forthcoming.

Energy and Entropy.—The decomposition of any form of energy into two factors, one of which is of a constant magnitude, says *Nature*, introduces certain simplifications into the theorems of thermodynamics and chemical physics which appear to merit some attention. Herr W. Meyerhoffer, in the *Comptes Rendus*, points out that the constant factor in the case of heat is not the entropy, as maintained by M. Le Chatelier, but the absolute specific heat, which has the dimensions of an energy divided by degrees of temperature. Entropy, on the other hand, is an energy divided by a number representing the number of degrees possessed by the heat at the time of its passage, and which Herr Meyerhoffer proposes to call the number of the isothermal. The confusion between entropy and absolute specific heat arises from the fact that the dimensions of temperature are at present unknown. Herr Meyerhoffer proposes to call the two factors of energy capacity and potential respectively. Then every transfer of heat will involve a change of two potentials, and the criterion of a reversible process will be the inequality of the two potentials. All the cycles invented since Carnot have always had the same function of transforming the variation of one potential into that of another of different nature. By means of this division of energy, most of the known stœchiometric laws can be reduced to one, thus:—The smallest particles of matter have, in a comparable state, the same capacity of energy. By going through the various forms of energy, Regnault's law concerning the specific heats of gases, and the laws of Dulong and Petit, Faraday, Eötvös, and Dalton may be severally obtained.

The Want of Light in Public Conveyances.—The great companies that carry the travelling public, says the *Lancet*, whether in omnibuses or in railway carriages, display a very inadequate sense of their duty in the matter of providing light. Last year it seemed as though the General Omnibus Company was about to set an excellent example. It introduced the electric light into the centre of the omnibus, instead of the oil lamp at the door that only seemed to make the gloom of the inside more depressing. At first it seemed as if the passengers would be able to beguile the time by reading newspapers or books; but the light has become small by degrees, and is altogether inadequate for any such pleasant purpose. On the railway lines, with but few exceptions, the same semi-darkness reigns. The Midland Railway, we believe, has a few trains on the main line fitted with the electric light; but we lately travelled about twenty miles in practical darkness. The Great Northern Railway has attempted to do its duty in this matter in some trains, but has receded rather than advanced in the attempt. The South-Eastern Railway has tried the slot system in some of its trains, and for one penny the passenger could get half-an-hour's light to read by, but on the whole the companies favour darkness rather than light. We protest strongly against the persistence in this state of things as one altogether out of date. Men and women spend too much of their time now in travelling for this to be tolerated. Our protest is in the interest of the public and of the eyes of our patients, but the interest of the railways and the omnibus companies would also surely be served by the reform, and we strongly advise the public to patronise the company that is most generous in the matter of providing efficient light.

Smokeless Combustion.—Some trials at Berlin for securing complete combustion with the absence of smoke have, it is stated, induced the North German Lloyd and the Hamburg American Packet Company to adopt the system, which is thus described:—Coal, reduced to powder—not necessarily very fine, however—in centrifugal disintegrators, is introduced into a pear-shaped combustion-chamber lined with firebrick, and fitted with an induction apparatus like those used in petroleum-fired furnaces, the coal-dust being drawn along by a jet of steam or compressed air. The combustion chamber, which takes the place of a furnace, is provided with two apertures, one in the centre line of the boiler—in case of such an application, for instance—occupying the position of the usual fire-hole door, while the other, on the opposite side of the combustion chamber, serves for introducing the coal-dust through a pipe, so placed that the dust is evenly dispersed over the whole extent of the chamber. After the first ignition of the dust, which may be affected by any source of heat, the combustion is said to continue very intensely and regularly under the action of the air current, which is regulated in accordance with the quantity of dust necessary to produce the degree of heat for the required amount of steam. The air or steam and coal-dust are intimately mingled in the zone of combustion, while the speed of the current, which has served as a vehicle for the dust, is very much reduced. Each particle of fuel held in suspension is, by this method, brought into such intimate contact with the oxygen necessary for its combustion, that this combustion is so complete as to allow scarcely any smoke to be perceptible. In inter-mural electric light stations, where it is very desirable to minimise the smoke nuisance, some such system as this will probably prove to be valuable.

The "Philosophical Magazine."—The October number of the *Philosophical Magazine* contains several Papers of electrical interest. The number opens with a Paper by Prof. J. J. Thomson on "The Effect of Electrification and Chemical Action on a Steam-Jet, and of Water-Vapour on the Discharge of Electricity through Gases," which deals with the formation of water drops under various conditions of pressure, temperature, and electric stress, and refers the effects of chemical action on steam-jets to a condition of electric stress caused by atomic charges. The Papers by Lord Kelvin "On the Piezo-electric Property of Quartz" and "On a Piezo-electric Pile," which we published in abstract, and which were read at the British Association this year, are published *in extenso*. Mr. J. Trowbridge contributes a Paper "On the Oscillations of Lightning Discharges and of the Aurora Borealis," in which the artificial conditions of experimental sparks and discharges and the natural conditions under which lightning flashes and auroræ occur, are compared. It is puzzling that, in Papers of this sort, we never hear anything of the Aurora Australis—it is always the northern phenomenon which is discussed. An extract from this article will be found in another Note. The Note on "Endothermic Reactions Effected by Mechanical Force (First Part)," by M. Carey Lea, is interesting when considered in conjunction with the piezo-electric property of crystals, &c., described by Lord Kelvin. It deals with various endothermic chemical reactions produced by mechanical pressure, and concludes with the general deduction "that mechanical force can bring about reactions which require expenditure of energy, which energy is supplied by mechanical force precisely in the same way that light, heat and electricity supply energy in the endothermic changes which they bring about." Dr. Sophie Bryant contributes an application of determinants to an example of "Correlation of Averages," where there are four variable quantities, a subject which, though somewhat beyond the range of everyday work, is not without interest to electricians.

ELECTROMAGNETIC THEORY.—LV.

BY OLIVER HEAVISIDE.

(Continued from page 519.)

§213. First, as regards long land lines, of say 400 miles in length (which is a long distance in this small country), leakage presented itself as an unmitigated nuisance. The worst case of all was during a continuous soaking rain all over the country. When this had gone on for a few hours the insulation resistance fell so low, by leakage over the dirty wet insulators mostly, though assisted by contacts with wet foliage, &c., that many of the important circuits were completely invalided, the received current (even with increased battery power) being too small for practical use with the instruments concerned. This was usually the case in the U.K. on any very wet day. But it was also the same in effect in the E. and I., although not so many lines were invalided, nor did they break down so quickly.

Incidentally, it may be mentioned here that the so-called "earth-currents" (meaning currents *in the line* itself), occurring during magnetic storms, such currents being a manifestation thereof, did not seem to mind the leakage much, perhaps because their E.M.F. was not like that of a battery at one end of a line, but acted continuously along the circuit, by a continuous slow change going on in the earth's magnetic force, or, rather, in the magnetic force in the air surrounding the earth. Probably the "earth-current" goes the same way in the line as in the earth (provided the line is not set at right angles to the real earth-current), whereas when a battery is used, the earth and line-currents are opposed. But it is not easy in wet weather to get a good magnetic storm, so that close observations can be made regarding the influence of leakage on earth-currents. We may dismiss them, and sum up that, as regards land-lines, leakage does not seem to have a single redeeming feature.

The effects of leakage next presented themselves to me on cable circuits with land-lines attached, and were exceedingly curious. There were two circuits of the kind, but one in particular had a varied history as regards leakage. It was a cable of about 400 or 450 miles running east and west, having a land line of 120 miles at the east end, and one of 20 miles at the west end. The apparatus used was the Wheatstone automatic, that is, an automatic transmitter and a polarised receiver, recording dots and dashes, and the working was done without condensers, by utilising the earth direct to complete the circuit.

The best results were obtained in fine dry weather with a hard frost—the harder the better. The insulation of the long (east) land line was then at its highest, and the signalling could be done up to 30 words per minute or a little more from west to east, though considerably less the other way, for a peculiar reason. But this was quite exceptional, and did not last long. The next best was in any very dry weather. But in ordinary average fair weather, not rainy or damp, the speed was much lower, say 24 or 20 words per minute. The effect of rain was always to lower the speed, perhaps down to 15 words per minute. A leakage fault on the land line or a contact with another wire had a similar effect, only worse, provided it was a bad fault, and the speed would go down to 10 words per minute or less. Now it is possible that the extra good results obtained in a hard dry frost arose partly from the reduced resistance of the east land line (the usual iron wire), but there was no doubt at all that the main cause of the wide variations of speed was leakage on the land lines, especially on the long one, of course.

Now it is to be noted here that in the former case of long land lines the leakage was prejudicial by the attenuation it caused, whereby the received currents were made too feeble to suit the apparatus. The working speed, though relatively fast, was too slow for any notable distortion of signals in transit by the condenser action so marked in cables. But in the latter case, of a cable with terminal land lines upon which similar leakage occurred, the prejudicial effect was not due to the attenuation. There was plenty of current—in fact, a superabundance—but it did not come out at the receiving end properly shaped for making dots and dashes, except at a greatly lowered speed. It should also be understood that the actual speed of working was always pushed up to the greatest possible (the press of business being such as to make 25 hours work per day all too short), and that the automatic character of the signalling made the fixation of a limiting speed, without complete failure of any marks, quite definite at any particular time. Practically, however, the working speed was pushed a good deal higher than this limit by making regular use of mutilated signals. Now it was proved by daily experience that there was a remarkable sensitiveness to damp, or leakage of any kind, the speed of working, conditioned by the reception of good marks, going up and down like the barometer, though with a far wider range than that instrument. The east land line was so manifestly the offender that it came in for a great deal of blame. Yet it was not a bad line by any means, and its leakage would have passed unnoticed, had there not been such a peculiar lowering effect on the speed connected therewith.

But how about leakage in the cable itself, seeing that the above results were so out of harmony with what they should have been, by general reasoning regarding retardation? This question was soon answered by the automatic development of a first-class leakage fault in the cable. Its effect on the speed was substantially the same as that of leakage on the land-line. It lowered the speed, and since it was always on, the effect was permanent. The ordinary fluctuations disappeared in a great measure, as of course did the fine weather high speeds. It was like continuous heavy wet. As the fault got very bad the speed went down to 10 words per minute or less, in spite of increased battery power.

On describing this prejudicial effect of leakage to the electrician of the cable ship which came to remove the fault (it was the late Mr. S. E. Phillips, of Henley's), he assured me I was quite wrong. It was impossible for a leak to act like that. So said the captain, too. It was known, said they, that a leak was an excellent thing. It had been found so on the French Atlantic not long before, and in other cases. I fully believed this, because it seemed theoretically sound, and I had heard similar statements before. But they did not assist me to an understanding of the patent fact that leakage could be highly prejudicial instead of beneficial. In corroboration of this, when the fault was removed, the speed went up again, and the normal state of things was restored.

The next stage in this history was the arrival of that wonderful instrument, Thomson's recorder, which had been recently brought out. It was the original Atlantic cable pattern, with 20 big tray cells for the electromagnets, and a batch of smaller ones for the mousemill and driving gear. This instrument simplified matters greatly, for the current could be considered as and seen to be a continuous function of the time, whereas with the polarised recorder of Wheatstone (an instrument quite unsuitable for cable work) the variations of the current could be only roughly guessed.

Now, a peculiarity of the siphon recorder was that no definite limiting speed was fixable. If one person thought 40 words per minute fast enough for good marks; another, more practised, would as easily read them at 50 or 60, and even manage to make them out at 70 words per minute, though the last was undoubtedly rather troublesome. The automatic transmitter being still used, the dashes became big humps, and the dots little ones, on the recorder slip, and at 70 words per minute, although the big humps were plain enough, the little ones were mostly wiped out, though it could be seen where they ought to have been, so that some reading was possible. The absence of a definite limiting speed under given circumstances introduced a fresh complication. Nevertheless, a careful study of the recorder slips taken at various speeds, but particularly in the neighbourhood of the critical speed for the polarised recorder, proved that the plain result of general reasoning that leakage should be beneficial in general was certainly true, and, moreover, furnished a partial explanation of the anomalous behaviour of the polarised recorder.

The siphon (Thomson) recorder, with its shifting zero, was sublimely indifferent to the vagaries of the current which were so distructive of intelligible marks in a dot and dash instrument, so that ordinary leakage passed quite unobserved as a rule. Nevertheless, it was plainly to be seen that when there was much leakage the result was to improve the distinctness of the

Digitized by Google

marks by reducing the range of variation of the current from the zero line, and improving the dots, or small humps, relatively to the dashes, or big humps, which were reduced in size.

But, to clinch the matter, a second leakage fault appeared in the cable whilst the siphon recorder was on, and rapidly developed. Now, it was only at the west end that there was a siphon recorder; at the east end was the polarised recorder. The result was that the speed from west to east went down greatly as the fault developed, in accordance with prior knowledge. But the other way, from east to west, receiving with the siphon recorder, the working was greatly improved. The ultimate result was that when the fault got very bad no marks at all could be got at the east end, even by key-sending, owing to the great attenuation, whilst we could receive first rate on the siphon recorder at the west end. On the very last day, when communication from west to east had to be done by a roundabout course, we were able to receive a long batch of, I think, 150 messages at high speed (about 55 or 60 words per minute) by using 80 Leclanché cells at the sending end, and putting on the electromagnets all the tray batteries available, including most of the small ones, to magnify the marks. Now this might seem to be merely a testimony to the sensitiveness of the instrument. But the significant point was that although the marks were very small, in spite of magnification by increased battery power at both ends, they were exceedingly clear. They were the best ever got at the speed. We were practically working past a fault of no resistance, for the cable soon gave up the ghost. The tail end of the big batch finally degenerated to a straight line, indicative of a very dead earth.

On the removal of this fault, the received current was largely increased of course. But, simultaneously, the distortion of the marks on the siphon recorder became huge at the speed 60. It needed to be much lowered to give conveniently readable marks.

§ 214. Now the above facts gave a decisive and cumulative proof that leakage was beneficial even when concentrated at a single spot, provided the current-variations were recorded in a simple manner. But a complete explanation of the very large decrease in the speed possible when the polarised recorder was used, turned out to be rather a complicated matter in detail, although sufficiently simple in the fundamental principle. This effect, so detrimental to an efficient use of the cable, was mixed up with another one, viz., a difference in the working speed according to direction, of say 25 per cent. (with the same instruments), but variable with circumstances. This effect, again, seemed to have two causes, one depending upon the circuit, and the uncentrical position of the cable in it, independent of the kind of instruments used; whilst the other was special and peculiar to the automatic transmitter and receiver when combined with the uncentrical position of the cable. It may be readily imagined that the resultant effect on the working speed requires some study to be understood. It will be sufficient here to mention the instrumental peculiarity in its relation to the detrimental effect of leakage.

The original automatic transmitter of Wheatstone was constructed to make dots only upon the slip of a special receiver; there were two rows of dots, one set being for the dots, and the other for the dashes of the Morse code. But when the inventor wanted the E. and I Co. to take it up, they demanded dots and dashes, as usual. So the instruments had to be modified. Now I have personal reason to know that a few years later the inventor was quite at sea as to the reason of the peculiar effects observed in working his instruments on composite circuits and cables. It is therefore pretty safe to assume that previously, when the conversion was made, the manner of the conversion, from making double dots to dots and dashes, was dictated purely by considerations of mechanical convenience, and this conclusion may be made nearly certain by a comparison of the original with the modified transmitter. But Mr. Stroh knows all about it. At any rate, the peculiar way of making the dash and the long space was the cause of all our trouble with leakage, which cost the Company an immense sum of money, viz., what they might have gained otherwise, for they were blocked with work, and might have had much more.

To make a dot, a short positive current was sent, immediately followed by a similar short negative current. To make a dash, after sending the first short positive current, there was an interval of no current lasting twice as long as the first current, followed by a short negative current which terminated the dash. Similarly, to make a long space, a short negative current came first, then an interval of no current, and finally a short positive current. Now in these intervals of no current, the sending end of the line was insulated. When sending current, on the other hand, the line was to earth, through the battery. Two distinct electrical arrangements were therefore operative in turn, viz., a cable with both ends earthed, and a cable with only one end (the receiving end) to earth. If the former system always prevailed, the manner of transmission of electrical changes would follow one law. If the latter system prevailed, it would follow another law, and would give much greater retardation. In real fact, the two ways were in alternate action irregularly. This has to be considered carefully in examining the influence of the uncentrical position of a cable in a composite circuit, and also of leakage.

Now the practical effect worked out thus. There was a real positive and material advantage in making the dash and long space of the Morse code by a short initial current instead of a long one, as in ordinary working with reversing keys. I estimated the gain as amounting to from 100 to 125 per cent. under favourable circumstances. This implies that the limiting speed is really worked up to. But it was vitally necessary to secure this advantage, that the insulation should be very good. A peculiar balance had to be preserved between the positive and the negative currents. The currents were of equal duration and of alternate signs, but necessarily not equidistant in time. Now, with exceedingly good insulation, the short current sent at the beginning of a dash was sufficiently prolonged in reception as to not merely make a good dash firmly, but to keep the balance for the next currents. But if you put a fault on the line, and let the charge leak out during the dead interval of the dash, then the next following negative current terminating the dash, would be too strong, so that an immediately succeeding positive current (with a negative current after it) to make a dot would miss fire altogether. Similar remarks apply to the dash. If the negative current that initiated the dash were allowed to die away by the action of a leak, the next following positive current would be too strong, and cause an immediately following current to miss fire. Remember that the reception of the signals was with a polarised recorder, the zero of which could not be continuously altered to catch the missing currents except by a very artful person who knew what was coming, and was quick enough to alter the regulation exactly at the right moments. It will, by the above, become roughly intelligible how a leak, actually quickening signals in a remarkable degree, can yet be most prejudicial in a special system of signalling requiring the preservation of a sort of balance. If the siphon recorder be substituted the necessity of the balance disappears; but the marks would be very hard to read at the same speed. To make them readable the speed should be at least doubled. The dashes will then become well-formed humps.

The reader who may desire to pursue the subject of leakage effects further may be referred to my "Electrical Papers," Vol. I., especially p. 53, for continuous leakage, p. 61 for more details relating to the above-described case, and p. 71 for the general theory of leaks, which is fully worked out in several cases to show the expediting effect. I also there propose artificial leaks. The following extract (p. 77) is easy to read, and so may be worth quoting:—

"When a natural fault, or local defect in the insulation, is developed in a cable, it tends to get worse—a phenomenon, it may be observed, not confined to cable-faults. Under the action of the current the fault is increased in size and reduced in resistance, and, if not removed in time, ends by stopping the communication entirely. Hence the directors and officials of submarine cable companies do not look upon faults with favour, and a sharp look out is kept by the fault-finders for their detection and subsequent removal. But an artificial fault, or connection by means of a coil of fine wire between the conductor and sheathing, would not have the objectionable features of a natural fault. If properly constructed it would be of constant resistance, or only varying with the temperature, would contain no electromotive force of polarisation, would not deteriorate, and would considerably accelerate the speed of working. The best position for a single fault would be the centre of the line, and perhaps ½ of the line's resistance would not be too low for the fault"

Digitized by Google

The effect of one leak is marked, perhaps 40 per cent. What *does* this represent in £ sterling? How many thousands or tens of thousands of pounds' worth of copper and g.p., &c., would be equivalent? If one leak would not quite do it, then two would.

But to have only one or two leaks is to look upon the leak as a dangerous nuisance. Although the best position for a given amount of leakance *in a lump* is in the middle of the cable, yet to have the given leakance in a lump is the worst arrangement as regards its accelerative efficiency. The best arrangement is uniformly-spread leakance, as much as possible, with, however, a thoroughly useful residual terminal current to work with, which current could be varied far more rapidly than is possible with a single leak.

Is it impossible to find an insulator of comparatively low resistance which should be suitable in other respects? Telegraph cable manufacturers would probably say, No. That, however, need not be considered conclusive, because, as is well known, when an industry or institution is once established, it always gets into grooves, and has to be moved out of them by external agency, if at all. But should such an insulator be unattainable, then the only alternative is to have artificial leaks, as many as possible. The theory is, I think, quite plain, and I know that the practice is also, up to a certain point. But here be grooves again. For people working in established ways have their own proper work to do, and have no time to waste upon "fads." So much is this the case that it often happens that they have exceedingly little knowledge of how things would work out if they departed from the ruts they are accustomed to run along. That is to say, the spirit of scientific research, which was to some extent present in the industry in its early stages, has nearly all evaporated, leaving behind regular rules and a hatred of fads. I am no wild enthusiast, having been a practician myself, but it has certainly been a matter of somewhat mild surprise to me that cable electricians, who have had such unexampled opportunities in the last 20 or 30 years, say, should have done nothing in the matter of leaks. Perhaps there may turn out to be objections at present unthought of. The same could be said of anything untried. Several cases of resistance to change of established practice, where the changes ultimately turned out to be of great benefit, have come under my personal observation. The proposed changes were (I believe quite honestly) first scouted as fads, and the innovator was snubbed; next, under pressure, they were reluctantly tried; thirdly, adopted as a matter of course, and the innovator snubbed again. But this is the nature of things, and can be seen everywhere around—very notably in the political world.

(To be continued.)

THE HILL TESTING SWITCH.

A testing switch has been designed by Mr. Alex. Hill, of Hong Kong, for use more particularly on board cable repairing steamers and stations having to make frequent tests. The switch, as shown in the illustration and by the diagrams, gives instantly, by simply moving the lever, combinations for four tests constantly in use, and in its fifth position leaves the instruments disconnected, and ready to be joined up in any way the electrician pleases.

It will be seen in Fig. 1 that by means of the long lever handle, which is attached to the pivotted barrel, it is possible to throw the switch into several positions for the various tests; while, by means of the notches in the slotted plate shown in Fig. 2, the handle is firmly fixed in position. This slotted plate permits of two positions requisite for the Kennelly test, one each for the dielectric and copper resistance tests, and one for leaving the switch springs "free." On the barrel, which is turned round by the motion of the lever, there are three cams, which press against the switch springs and move them towards or away from the fixed contacts. The successive positions of the lever enable the circuit connections to take the forms shown in the Figs. 3 to 8. The quick change from, say, D R (dielectric resistance) to C R (copper resistance) is of great importance on a cable ship when time, owing to uncertainty of weather, is generally very scarce.

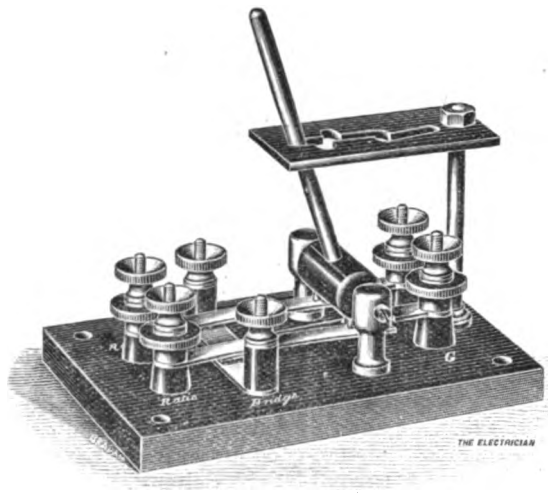

FIG. 1.—Hill's Testing Switch.

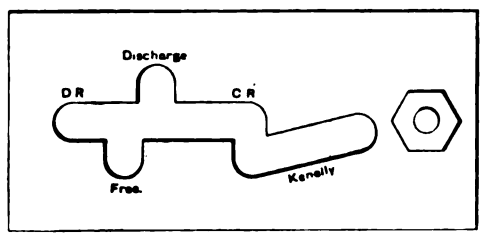

FIG. 2.—Plan of Moveable Slotted Plate

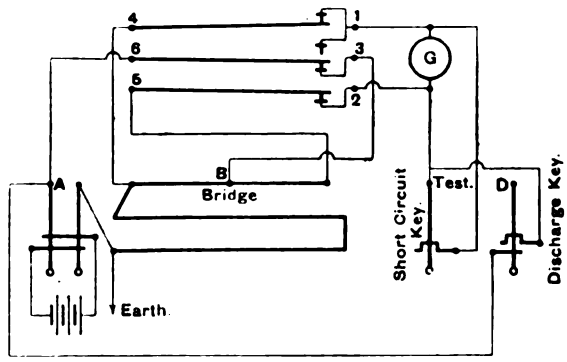

FIG. 3.—Complete Diagram of Connections for C.R. Test. The wire to be tested always goes on *Test Terminals*, except for Discharge Test, when Screw D of Discharge Key is used.

AN EXAMINATION OF PROF. LODGE'S ELECTRO-MAGNETIC HYPOTHESIS.

BY PROF. J. H. POYNTING.

(*Continued from page 577.*)

The most evident phenomenon characterising the electric current is the magnetic field around it. This we may regard as manifesting the existence of so much magnetic energy in the neighbourhood of the conducting wire. Let us see how the hypothesis will account for this energy. The first step is to reduce permanent magnetism and current magnetism to one species by adopting Ampère's theory. If we consider a small closed current-bearing circuit, observation tells us that, at a distance from the circuit, the field is indistinguishable from that due to a small steel magnet, with centre in the plane of the circuit and axis perpendicular to it. Starting from this, we know that we can deduce an arrangement of permanent magnets, equivalent as regards the outside field to any current-bearing circuit. The circuit differs magnetically from the steel in two respects only, viz., that it requires a continual supply of energy to maintain it, and that we can get into its inside. This last difference may be merely due to the large size of any apparatus at our command, and it is quite thinkable that, if we could make ourselves or our apparatus smaller than molecules, we could explore the inside of the steel molecules. The other difference is possibly not one of the kind; for suppose the resistance to be diminished till it disappears, the rate of energy supply, C^2R, disappears also, and we have a current circuit—never mind how the current was started—which is as permanent a magnet as a steel bar. It is a short and inevitable step from this to Ampère's hypothesis that a magnetic molecule—a molecule of steel, say—*is* essentially a small closed perfectly-conducting circuit with a current of electricity in it; or, in terms of Dr. Lodge's hypothesis, either two equal and opposite currents whirling round at equal speeds in opposite directions in each molecule, or a positive whirl in one direction in one molecule, accompanied by a negative whirl in the other direction in the next molecule. We may dismiss this duality for the present, on condition that it comes up for sentence when called upon, and return to the single circuit. Such a circuit, when placed in a magnetic field, behaves, doubtless, like finite circuits, and tends to set itself perpendicular to the lines of force, and with its own lines parallel to the lines of the field, and in the same direction through the circuit. It tends to move from weaker to stronger parts of the field—tends, in fact, to include as many positive and exclude as many negative lines as possible.

But the disappearance of resistance has a peculiar effect Even a circuit of the resisting kind, with which alone we have practical acquaintance, would protest against the inclusion of foreign lines of force in addition to its own, and the current would diminish while they were being included. An ampere circuit would not merely protest, but would absolutely prevent any change in the total number included, for any increase would be accompanied by a finite negative E.M.F. proportional to the rate of increase, and therefore by an infinite current, since R is zero. This is not to be accepted as possible, so that all that can happen is that some of the current's own lines of force shall be replaced by those of the field, and there is a consequent weakening of the current.

When a mass of iron consisting, we suppose, of such ampere currents is brought into a magnetic field, all the circuits tend to turn round to include the lines of the field, and at the same time the ampere currents decrease in strength. The circuits thread themselves like beads on to the lines of force of the external field, their currents falling as they thread on. But their own surviving lines of force are added to those of the field, so that the total field is greater, and the iron has greater permeability than a vacuum; or perhaps it will be better here to say that the iron *conducts* the lines of force better than a vacuum would, for permeability has an exact significance, not quite describing the property now under discussion. As new lines of force are added to the field the iron will conduct them better than a vacuum, until every molecule has all its lines brought into service, and its current, therefore, reduced to zero. After this point is reached, since the molecules either will not take any more lines of force, or if they take any more will establish negative currents to neutralise them, they are worse conductors than a vacuum, for they fill up part of the space uselessly or injuriously. They will therefore tend to move from stronger to weaker parts of the field, as if diamagnetic. Some indication of such a change in conducting power has been detected by Ewing in the magnetisation of iron in exceedingly strong fields, for though the permeability or induction produced / the field producing it—both reckoned from zero—was always greater than 1, the value of increase in induction / increase in field producing it, or the conducting power, as I have called it, fell ultimately below 1.

For some reason, not yet explicable, the magnetic chains in iron become unstable, and break up when the temperature is raised to the neighbourhood of 800deg. The iron then is practically equivalent magnetically to any other substance above this temperature.

Assuming then that we have some notion of what we mean by currents of electricity whirling in channels of no resistance, Ampère's hypothesis gives us a fair explanation of iron and steel magnetism. If we accept the view that the interior of a magnet does not differ from the exterior in kind but only in degree and in permanence, we may attempt to extend the hypothesis to explain the magnetic qualities of all other substances, *i.e.*, their power of carrying the lines of force, and of carrying them in slightly different degrees.

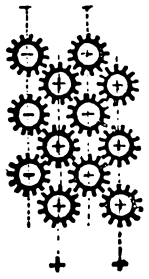
Let us think of the lines of force in air circling round a current or passing from pole to pole of a magnet. We may think of these as passing through a number of electric whirls, or at any rate through perfectly conducting rings ready to exist as whirls. Before the passage of the lines of force these rings are turned in all directions. After the passage they tend to set perpendicular to the lines of force. If the medium is paramagnetic we may suppose the rings to have initial currents in them; if it is diamagnetic we may with Weber suppose that they have no currents initially, and when no lines of force pass through. On the establishment of the field negative currents are excited of such value as to make negative lines of force thread each ring equal in number to the positive lines sent through by the field. Thus each ring acts as a part of the field through which no lines of force pass, and the permeability is thereby diminished. At the same time the diamagnetic substance will tend to weaker parts of the field, and we have the main facts of diamagnetism explained. There is a serious difficulty in the nearly constant permeability, differing only by a very small amount for a diamagnetic solid like bismuth and a magnetic gas like oxygen, the one with its molecules crowded together, the other with its molecules comparatively wide apart. Perhaps we can strengthen this weak point by supposing the conducting rings of very different diameters in the two substances, or we may think of the electric channels as different altogether from the molecules and the same in number per c. c. in bismuth and in oxygen. Another difficulty lies in the non-existence of permanent magnetism except in iron, nickel, and perhaps cobalt, but it is no greater than the difficulty with iron above 800deg. Perhaps both will ultimately find the same explanation, and until this is forthcoming we need only say that Ampère's hypothesis is merely silent on the point and is not necessarily unable to explain it.

Now as to magnetic energy. Dr. Lodge points out a number of facts which suggest that magnetic disturbance is of the nature of spin round the lines of force. The amperean circuits at once present themselves as being the seat of this spinning, and the electric fluid or fluids in the channels as the spinning material. These whirlings of electricity, either in themselves or in the accompanying motion of the entangled matter (Maxwell, by the way, thought it was the matter), possess, according to Dr. Lodge, the magnetic energy of the system. In fact, they are themselves magnetism.

So far we have been dealing with magnetism and its relation to electricity, the space-filling fluid, and we have come to the conclusion that magnetism consists of vortices in this fluid. It remains to explain the nature of the ordinary electric

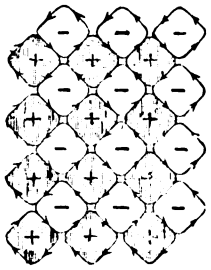
Digitized by Google

rrent, and the way in which its accompanying magnetic ld is maintained. Dr. Lodge uses for the purpose a echanical analogue or mechanical model, a modification of axwell's well-known model, which is described in his Scientific Papers," Vol. I., page 451, and I believe by Dr. arnett in "Maxwell's Life."



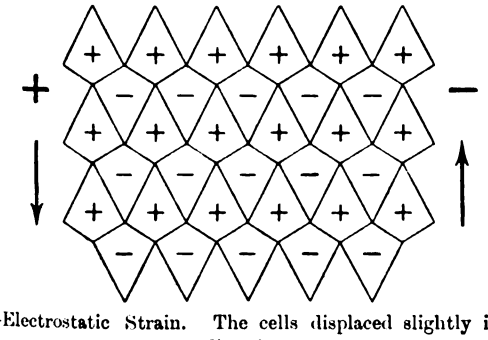
R. LODGE'S FIG. 36.—Rows of Cells Alternately Positive and Negative, geared together, and free to turn about fixed axes.

Let us imagine the two fluids, which are to be regarded as intly filling space, to have a cellular construction, each consisting of spheres or little india-rubber bags, or what you like, n contact with each other. In dielectrics we think of conguous cells as gearing in some way. Let these cells, when in magnetic field, be spinning round the lines of force, the ositive in one direction, the negative in the opposite; and et positive and negative be alternated so that the opposite notions may be possible without slip of gearing.



DR. LODGE'S FIG. 37.—Section of a Magnetic Field, perpendicular to the lines of force; alternate cells rotating oppositely. (Another mode of drawing Fig. 36.)

Fig. 37 from Dr. Lodge's book illustrates this idea when he lines of force pass into the paper from above, the axis f spin, therefore, being perpendicular to the paper. We may further materialise the conception by inserting teeth round the dges of the cells; and here the family likeness to the parent Maxwell's model) becomes stronger. We then have Fig. 36. If we suppose Fig. 37 to represent the unstrained state in a dielectric, then electrostatic strain will be represented by ome such deformation as that represented in the figure below

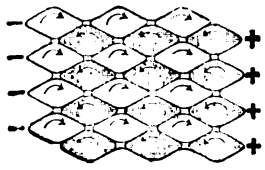


IG. A.—Electrostatic Strain. The cells displaced slightly in opposite directions.

Fig. A); not, I think, in the manner represented by Fig. 46 n Dr. Lodge's book.

If we take Fig. 36 as our type, it is easier to think of the wheels as being attached to some kind of framework. We may think of all the positive wheels in Fig. 36 as arranged lat against one series of parallel rods going down the page, and the negative wheels on another intermediate and parallel series. We may think of the wheels, or their teeth, as not quite rigid, so that when the positive rods are pulled down and the negative up, there is a slight relative displacement and energy is stored, and this will represent an electrostatic strain. Probably, if we arranged all the forces properly, we should be able to do without the framework of rods. Meanwhile I find I cannot think of the model clearly without it.

The distinction between a dielectric and a conductor is to be represented by the abolition of the teeth on the wheels in the conductor. The surface of the wheels are in contact, and are only more or less rough—viscously rough, rather than frictionally rough. It appears rather difficult to think of the layer of wheels separating a dielectric and a conductor, for on the dielectric side they must have toothed gearing, and on the conductor side they must only rub; but we may get over the difficulty by supposing these wheels double, one toothed to gear on the dielectric side, and the other untoothed to rub on the conducting side, and both keyed on the same axis.



DR. LODGE'S FIG. 46.

Dr. Lodge regards a current as represented by a slip of one row of wheels against the next. He says (p. 206), "Notice that in a medium so constituted and magnetised—that is, with all the wheel-work revolving properly—there is nothing of the nature of an electric current proceeding in any direction whatever. For, at every point of contact of two wheels, the positive and negative electricities are going at the same rate in the same direction; and this is no current at all. . . . A current is nevertheless easily able to be represented by mechanism such as that of Fig. 36 or 37; for it only needs the wheels to gear imperfectly and to work with slip. At any such slipping-place the positive is going faster than the negative, or *vice-versâ*, and so there is current there. A line of slip among the wheels corresponds therefore to a linear current. . . . Understand: one is not here thinking of a current as analogous to a *locomotion* of the wheels—their axes may be quite stationary. The slip contemplated is that of one *rim* on another."

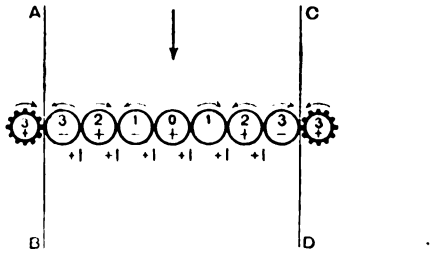


FIG. B.—Cells Slipping in a Wire carrying a uniformly distributed current.

Thus in the figure above (Fig. B), let the row of wheels represent the cells across the diameter of a wire carrying a steady current, A B C D representing the section of the wire. Let the speeds of rotation of the wheels be as marked on each. The resultant positive slip is +1 at each surface of contact, a total of 6.

It is perhaps presumptuous to quarrel with a parent such as Dr. Lodge as to his mode of developing the faculties of his own offspring, but I must venture here to differ from him entirely in the way in which he seeks to make his model represent current. It appears to me that he has grafted on to his own model the representation of current in the entirely different model of Fitzgerald, and so obtains something quite inconsistent with his previous ideas. It is only by stopping short at the centres of the bounding wheels that he can obtain a resultant flow in one direction. Obviously, if he took in a whole number of wheels, each entire, he would get no resultant flow, for the flow on the opposite sides of each wheel is equal and

Digitized by Google

opposite. Thus, in the figure, if he took into account the outer sides of the two last wheels in the wire, he would have −6 neutralising the previously obtained +6. Or, to put it in another way, if we draw a plane, say, above the line of centres, a tangent to all the wheels, there is evidently no resultant flow across that plane. And we can think of cases of slip when we have no reason to suppose there is current. Thus, if a bar of soft iron is placed axially in a magnetic field near the centre of the bar the lines of force are parallel to its length within and without the bar. According to Lodge, the electric whirls are very rapid within the iron, and comparatively slow in the air outside. There must, therefore, be slip at the boundary, and yet we have no dissipation of energy to indicate the existence of the current.

Another objection is that the model worked thus would make a difference in kind between the process of displacing in a dielectric, the equal and opposite motions of the two fluids which are leading to an electrostatic strain, and the current in a conductor. This is rather setting back the clock. Perhaps we have gone on too fast, and the difference *may* exist, but I think we should hardly accept the evidence of the model on the point.

What Prof. Lodge calls current appears to me then to be merely sudden change of magnetic intensity. If this is just criticism let us see if the model can be made to represent a true current. I shall take the case of a steady current in

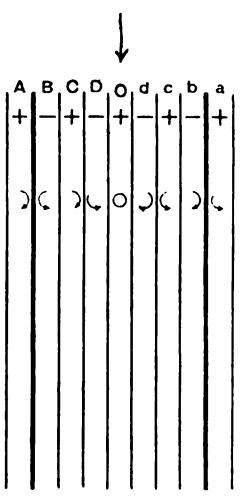

FIG. C.—Rods on which the positive and negative wheels are supposed to be fixed in the model of a wire carrying a current.

which the condition of affairs is not altering. It is always better to begin with such a case, just as it is better to begin with statics, hydrostatics, electrostatics, than with dynamics, hydrodynamics, and electrodynamics. When matters, or ethers, get into changing motion they are like the celebrated pig of the Irishman, difficult to count.

In the model we shall suppose that the current in the wire is represented by two equal and opposite processions of cells or wheels along the wire, and to help us in thinking of these processions we shall, as before, suppose two sets of rods parallel to the axis of the wire, the positive wheels on one set with their spindles perpendicular to the rods, and the negative wheels on the other set.

In the figure above (Fig. C) the rods alone are represented, directions of motion of the wheels on each being shown by arrows. The + rods are to be regarded as moving down the page, and the − rods up. The wheels on the bounding rods, B *b*, gear with the wheels on A *a* in the dielectric, but slip on those on C *c* in the conductor. Now, if the conductor extended through all space I do not see that the motions of the rods would involve rotation of the wheels. For any rod would be as it were surrounded by a symmetrical system, its wheels would not know which way to turn, and so would merely rub against their neighbours. But here the conductor is bounded by an insulating medium in which the rods can only move a very little way, and that only by straining the teeth of the wheels.

The result is that as B moves up past A its wheels behave as pinions moving on a rack in the place of A. They tend to turn the wheels of C in the opposite direction. These in turn tend to send round the wheels of D, and so on to O, the middle rod. Now, starting from the other side, *a* is at rest, and as *b* moves past it its wheels must rotate. This rotation is transmitted inwards, as before, to O. The result is that the wheels on O are urged in opposite directions from the two sides, and so remain at rest, while those of D and *d* rub against them. Those of C and *c* rotate faster than those of D and *d*, the friction due to the slip balancing that due to the slip of D and *d* on O, and so on, the rotation increasing outwards. When we come to B *b*, their wheels have the frictional resistance against the C *c* wheels on the inside, which must be balanced—since the motion is steady—by pressure on the outside against the A *a* wheels. Hence the B *b* wheels are not merely rolling on the A *a* wheels, but are pressing against them, and so turning them round. In other words, the rotation extends out into the dielectric. Thus, at the middle of the wire, there is no rotation—no magnetic intensity. It increases as we go outwards to the boundary, being in opposite directions on the two sides, and it exists in the surrounding medium. The rubbing of the surfaces, perhaps of the rods, perhaps of the wheels, dissipates energy which represents the heat appearing in the wire.

The model is probably indeterminate as to the way in which the energy finds its way into the various parts of the conductor, where it appears as heat. We might imagine the rods moved by end thrusts along the wire, their wheels setting the outside wheels spinning, or we might imagine a spin propagated along the outside wheels to the wire, and there setting the rods in longitudinal motion.

I have no doubt that the model would be able to represent the phenomena of the current induction when the motion is accelerating or unsteady, for Maxwell's model does this, and the differences of construction would hardly affect the point.

(To be concluded.)

THE APPLICATION OF ELECTROLYSIS TO QUALITATIVE ANALYSIS.*

BY CHARLES A. KOHN, PH.D., B.SC.

The first application of electrolysis to chemical analysis was made by Gaultier de Claubry in 1850, who employed the electric current for the isolation of poisonous metals, using platinum electrodes on which the deposition of the metal took place.

Other early workers followed in this direction, and in 1861 C. L. Bloxam published two Papers on "The Application of Electrolysis to the Detection of Poisonous Metals in Mixtures of Organic Matters" (*Jour. Chem. Soc.*, 13, 12, and 338). The author appears to have made extensive use of the methods described in these papers, and which have reference to the detection of arsenic, antimony, mercury, bismuth, and copper. The electrolysis was effected in acidulated solutions, from which the arsenic was evolved as hydride, whilst the other elements were deposited in the metallic state upon the cathode and subsequently tested, after dissolving, by the usual reactions.

Since the publication of these results the advances in electrolytic analysis have reference to quantitative methods only and the advantage of these latter for qualitative work has been, to some extent, overlooked. Within the last twelve years Classen and his pupils have placed a number of electrolytic methods for the determination and separation of metals in the hands of chemists, methods which have been added to by the labours of E. F. Smith, Vortmann, and others. These methods are of special value when applied to qualitative analysis in cases of medical and of medico-legal inquiry. They are not supposed to supersede in any way the ordinary methods of qualitative analysis, but to serve as a final and crucial means of identification and thus render it possible to detect very small quantities of the substances in question with great accuracy. As such they fulfil the required conditions admirably, being readily carried out, comparatively free from contamination with impure reagents and capable of being rendered approximately quantitative whenever desired.

The method devised by Bloxam for the detection of arsenic, in which all fear of contamination with impure zinc is avoided, has

* Paper read before Section B of the British Association.

Digitized by Google

been elaborated by Wolff (*Jour. Soc. Chem. Ind.*, 1887, p. 147), who has succeeded in detecting 0·00001grm. of arsenious acid by this means. It is in connection with the most important of the remaining mineral poisons that I have examined the applicability of these electrolytic methods, viz., antimony, mercury, lead, copper, and cadmium.

Antimony.—The method employed in the case of antimony is that adopted in its quantitative estimation by means of electrolysis, a method which ensures a complete separation from those metals with which it is precipitated in the ordinary course of analysis, arsenic and tin. This fact is of considerable importance in reference to the special objects for which these methods have been worked out.

The precipitated sulphide is dissolved in potassium sulphide, and the resulting solution, after warming with a little hydrogen peroxide to decolourise any polysulphides that may be present, electrolysed with a current of 1·5-2cc. of electrolytic gas per minute (10·436cc. at 0°C. and 760mm. = 1 ampere) when the antimony is deposited as metal upon the negative electrode. One part of antimony (as metal) in 1,500,000 parts of solution may be thus detected, a reaction thirty times more delicate than the deposition by means of zinc and platinum. The stain on the cathode, which latter is best used in the form of a piece of platinum foil about 1cm. in diameter, is distinct even with a solution containing $\frac{1}{20}$mgrm. of antimony, and by carefully evaporating a little ammonium sulphide on the foil, or by dissolving the stain in hot hydrochloric acid and then passing a few bubbles of sulphuretted hydrogen gas into the solution, the orange-coloured sulphide is obtained as a satisfactory confirmatory test. The detection of 0·0001grm. of metal can be fully relied on under all conditions, and one hour is sufficient to completely precipitate such small quantities.

Mercury.—Mercury is best separated from its nitric acid solution on a small closely-wound spiral of platinum wire. The solution to be tested is acidified with nitric acid and electrolysed with a current of 4-5cc. (cc. refer to cc. of electrolytic gas per minute). The deposition is effected in half an hour. The deposited metal is removed from the spiral by heating the latter gently in a test-tube, when the mercury forms in characteristic globules on the upper portion of the tube. As a confirmatory and very characteristic test, a crystal of iodine is dropped into the tube, and the whole allowed to stand for a short time, when the presence of mercury is indicated by the formation of the red iodide. 0·0001grm. of mercury in 150cc. of solution can be clearly detected.

Wolff has applied this test under similar conditions, using a special form of apparatus through which the solution to be tested is allowed to pass slowly, and in which a silver-coated iron electrode is employed as the anode.

Lead.—Lead is precipitated either as PbO_2 at the anode from a solution containing 10-20 per cent. of free nitric acid, or as metal, at the cathode, from an ammonium oxalate solution. In both cases a current of 2-3cc. suffices to effect the deposition in one hour.

Here again 0·0001grm. of metal in 150cc. of solution can be easily detected. With both solutions this amount gives a distinct colouration to the platinum spiral on which the deposition is best effected. As a confirmatory test the deposited metal is dissolved in acid, and tested with sulphuretted hydrogen, or the spiral may be placed in a test-tube, and warmed gently with a small crystal of iodine when the yellow iodide of lead is formed. The latter reaction is very distinct, especially in the case of the peroxide.

Of the above two methods that in which an ammonium oxalate solution is used is the more delicate, although it cannot be employed quantitatively owing to the oxidation that takes place on drying. An addition of 1grm. of ammonium oxalate to the suspected solution is sufficient. A great advantage of the electrolytic method as a crucial means for the detection of minute quantities of lead, lies in the fact that when the lead is deposited as peroxide from a nitric acid solution, it is completely separated from mercury, copper, cadmium, arsenic, antimony, and iron, none of which are deposited at the anode in this case. Manganese is the only commonly occurring element that behaves similarly.

This method is therefore of value for the detection of lead in water, citric and tartaric acids, baking powders, &c. If quantitative results for small quantities of lead are required, the best plan is to effect the electrolysis in nitric acid solution as above, employing a small platinum dish as the anode, to which the deposited peroxide, adheres well, and which can be weighed as PbO_2 after washing and drying at 110°C. May has suggested (*Z. f. Anal. Chem.* 14, 347) the ignition of the PbO_2 to PbO, and final weighing of the latter, but a loss always occurs under these conditions, which increases with the quantity of the peroxide present. This loss amounts to 2-3 per cent. on the weight of lead deposited.

Copper.—0·00005grm. of copper can be very readily detected by electrolysing an acid solution in the usual way. A spiral of platinum wire is employed as the cathode, and the presence of the metal confirmed by dissolving it in a little nitric acid and testing with potassium ferrocyanide. Quantitative results in solutions containing 0·001grm. of metal are thus obtained with considerable accuracy, and the method, as in the case of lead, is of use for the detection of minute quantities of the metal in waters. The advantages of electrolysis over the colorimetric methods usually employed in such cases are twofold. In the first place, concentration is not necessary, owing to the delicacy of the test; and secondly, the erroneous results that are obtained in all colorimetric processes due to the influence of the varying constituents present in the solution tested on the accuracy of the reaction are entirely obviated.

Cadmium.—Cadmium is deposited in the metallic state, both from potassium cyanide and from potassium oxalate solutions, the former of which is preferable. A current of 0·2cc. is sufficient, and 0·0001grm. of the metal can be thus detected. To confirm, the deposit is dissolved in hydrochloric acid, the solution diluted, and treated with sulphuretted hydrogen.

Detection of Metallic Poisons in Urine by Means of Electrolysis.—To apply the above methods in cases of poisoning, the organic matter with which the metals are associated must first be destroyed in the usual way by means of hydrochloric acid and potassium chlorate, and the solutions or precipitates obtained in the ordinary course of analysis then subjected, at suitable stages, to electrolysis. In such cases the advantages of electrolysis lie again in the delicacy and reliability of the tests and also in the fact that the small quantities of organic matter, with which the solutions obtained in such cases are contaminated, do not interfere with the electrolytic tests as they do with the ordinary wet tests By passing the current for a longer time than is required for ordinary aqueous solutions, the organic matter is decomposed, and thus prevented from affecting the reliability of the tests.

The detection of metallic poisons in urine can be directly affected by electrolysis.

The presence of *mercury* or of *copper* is detected by acidifying the urine with 2-3cc. of nitric acid (conc.), and electrolysing as described. 0·0001grm. of metal can be detected thus in 30cc. of urine, or 1 part in 300,000 of urine.

Lead does not separate well as peroxide from urine acidified with nitric acid, but if ammonium oxalate be added the reaction is quite as delicate as in aqueous solution, and 0·0001grm. of lead can be thus detected.

Antimony can be detected directly in urine, according to Chittenden (*Proc.* Connecticut Acad. of Science, Vol. VIII.), by electrolysis after the addition of 2-3cc. of dilute sulphuric acid; but this process was not found satisfactory. The better plan is to first precipitate by sulphuretted hydrogen, and then electrolyse as described.

In all these cases it is necessary to pass the current at least twice as long as when aqueous solutions are employed. In 24 hours a current of 1-2cc. completely decomposes urine, leaving a clear colourless solotion.

A comparison of the delicacy of these tests with the ordinary qualitative tests for antimony, mercury, lead and copper, by means of sulphuretted hydrogen, showed that in the case of antimony and of copper the electrolytic tests were one and a-half times more delicate, whilst with mercury and lead they were at least ten times more so. These comparisons were made in aqueous solutions.

In testing urine the value of the electrolytic method is still more evident, for the colour of the liquid interferes materially with the reliability of the ordinary qualitative tests when only small quantities of the elements referred to are present. This was well instanced in a case of suspected lead poisoning, in which the patient had been treated with potassium iodide. A direct test with sulphuretted hydrogen gave no reliable result even after standing 24 hours, whilst the deposit obtained on electrolysis gave a distinct *precipitate* of lead sulphide, after being dissolved in acid.

Other applications of the more reliable electrolytic methods of analysis to qualitative work can only offer attraction in special cases, and the data on the subject are to be found in the many electrolytic methods already published. It is by their judicious combination with the ordinary methods of analysis that a saving of time and labour and, above all, an increased reliability and accuracy are effected.

Split Car-Axles on Electric Cars.—There is, says *The Engineer*, a new electric car motor in process of construction in Chicago, which has two armatures so arranged that they may revolve at two different speeds, the fundamental idea at the basis of this peculiar construction being to secure a more ready and easy method of taking curves on street railways with the two armatures, it being found that the speeds are differentiated according to the radii of the two rails on every curve. The varying speed of the wheels on the outer and inner rails will, it is intended, do away with the friction incidental to the usual method of both wheels revolving at the same speed round the very sharp curves found on street railways.

MANCHESTER.

It is seldom that an opportunity can occur for the erection of so large a supply station as that which we describe elsewhere in our present issue. Manchester will profit, not only in the long run, but in the immediate future, by the deliberation with which an electric supply has been established. No straggling overhead system of wires had to be pulled down and written off, no inadequate attempts of speculative pioneers were to be bought up and shut down, nor has the City been divided up into arbitrary districts among competing companies. The early proposals were, however, more sound than was often the case seven or eight years ago. In 1886 the Manchester Electric Supply Company was founded "to light streets, public places, mines, ships, railways, tramways, or any other places or things by means of electricity or other similar agency; to create or produce electricity or other similar agency," &c. The Directors were Messrs. CROMPTON, ALBRIGHT, HOLMES, and VAUDREY. During the next year the highly successful exhibition was held at Manchester, and it might have been expected that the fine display of electric lighting, both in the buildings and in the gardens, would have borne some fruit in the lighting of the City. Messrs. MATHER and PLATT showed two 200 H.P. engines, each driving a pair of "Manchester" dynamos by link belts and jockey-pulleys, and the Brush Company provided nearly 600 arcs, some on masts in the grounds; and besides these were many other machines, good and bad. The only apparent result was the lighting of the Victoria Hotel, in 1888, by Messrs. HOLMES and VAUDREY, a hotel being a "place or thing" not otherwise specified in the prospectus of their Company. In the course of 1889 the Manchester Edison-Swan Company began to bestir themselves, and proposed to put down plant near Piccadilly for 10,000 lights. But the City Council had probably been watching developments, and because they owned the gasworks, rather than for modern socialistic reasons, which in themselves would have violated the recognised principles of the Manchester school of political economists, met to consider the question of a Provisional

Digitized by Google

Order in the summer of 1889. The Gas Committee offered no objection; and the Council discussed the serious prospects, on the one hand of compulsory lighting of an area, and on the other, of the action of the half-dozen companies who were already in the field, and who would scramble for an Order if the Council did nothing. The Mayor pointed out that the risk was not immediate; they had three years to turn round in, and were not obliged to commit themselves. The Order was obtained in 1890, and in the following year the Gas Committee appointed Dr. J. Hopkinson to draw up a scheme.

Although the five-wire system adopted by the engineer is the first example of its kind in this country, there is but little novelty about it. The possible demand for power might have resulted in a multiphase complication; or sub-stations with wonderfully ingenious automatic switches might have been tried. There will, of course, be many who would have liked to have seen alternate currents of some sort, and others will think the scheme only wants £25,000 worth of batteries at the station or in sub-stations, to make it perfect. One of the most striking features of the present state of the Manchester municipal power station, and one which a visitor cannot fail to notice immediately he enters the buildings, is the ample amount of space which has been arranged for extension of every department of the generating plant. In the vast machinery hall, the floor of which is even now completely roofed over, and which is provided with travellers throughout its entire length, there is space for about three and a-half to four times the present capacity of plant, and from ten to twelve times the present maximum of lamps. In the boiler house there is room for a considerable number of additional boilers; and by filling up an arm of the canal and building over the flooring thus acquired it will be possible to set a still greater number. The conduits, in like manner, have been constructed to take several extra feeders, while the copper which is already laid can carry a much greater current before its most economical current density is reached. Thus there would seem to be no prospect of the unhappy experience at some generating stations being repeated at Manchester, namely, of its becoming "pot-bound"—of its load increasing beyond the proper limits of its possible plant. There can be no doubt as to the wisdom in this particular case of such a high "factor of safety" for extensions as has been adopted in Manchester, even though the amount of capital which must be sunk in unremunerative works may be rather larger than is customary. For Manchester is certainly very late in its adoption of electric light and power; it is behind every leading city in the world in this respect; in fact, it is almost behind the proverbially trailing Bristol. Yet there can be no doubt that, the supply once offered, the citizens of Manchester will not be slow to avail themselves of it; and that, for some time to come, the engineers will find themselves very busy with new consumers. Situated as the power station is, in the midst of a manufacturing district, it is a matter for some surprise that, although some ten thousand lamps are already connected, there has been no demand whatever for motors. But for the similar apathy in London and elsewhere, one would have expected that attractive terms would have been offered to supply, if not factories, at all events small workshops with power during the day.

Into the vexed question of comparative merits of continuous and of alternating currents we need not now enter, nor will we urge that 410 volts is a step towards the adoption of high pressure supply as distinguished from low pressure, but we must express our great regret that, according to a scheme which has been submitted to the Local Government Board, it is proposed to provide an alternate-current supply for Salford. The two districts have long had their separate gas supplies; but with gas plant the load factor and its characteristics are of small importance, since storage is so easy and efficient. Still, that is no reason for the irrevocable separation which will be entailed if different systems are adopted. It is probable that the loads in the two districts will be materially different, and considerable benefit might result from a co-operation between them. The whole of the two areas would be none too large for a single system with two stations working together like those of the Westminster Company. The different London districts are ridiculously small, and this is due to the keen competition among the companies who were represented before Major Marindin. They were formed for the most part round scattered stations already existing, but in the course of time many combinations will doubtless be made either for the purpose of occasional co-operation, or for some comprehensive system of distribution of power generated at a distance. The station at Manchester is on an altogether different scale from these; and it may be expected that the Corporation will not only have reason to be proud of their electric supply, but will be able to show high economy in working expenses.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 584.)

Great care should be taken with the measuring instruments to see that they are correctly calibrated and can be relied upon all over their scales.

In measuring the power taken by a lamp with an ammeter and voltmeter certain precautions are necessary. If the voltmeter is connected directly to the lamp terminals, so as to indicate the volts on the lamp, the ammeter must of necessity be connected so as to measure the current through the lamp plus that through the voltmeter. On the other hand, if the ammeter is connected so as to measure the current of the lamp only, the voltmeter must be connected to measure the difference of potential over the lamp plus the ammeter. In the former case there will be an appreciable error, unless the voltmeter has a very high resistance compared with that of the lamp, and in the latter case there will be an error unless the resistance of the ammeter is so small as to be negligible in comparison with that of the lamp. Instruments can be made of such resistances that in either method of connecting the error is negligible.

A wattmeter may be regarded as a combination of a voltmeter and an ammeter, and is therefore liable to errors from the same cause. The resistances of the wattmeter cannot, however, be well made of such amounts that the error is negligible. It therefore becomes necessary to compensate for the error. This may be done by means of a double winding on the current coil, each winding having the same number of turns. The pressure coil of the wattmeter is connected directly to the terminals of the lamp. The lamp current plus the current through the pressure coil, therefore, passes through the main winding on the current coil of the wattmeter. The current through the pressure coil alone is, however, taken through the supplementary winding on the current coil in the reverse direction. The current of the pressure coil thus traverses the current coil an equal number of times in opposite directions, and its effect is, therefore, neutralised, and the instrument gives a correct reading of the power spent in the lamp. In order that the wattmeter shall have as wide a range as possible the current coil may be again wound in two equal

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

Digitized by Google

windings, which can, by means of a switch, be connected up either in series or parallel. This arrangement necessitates the compensating winding being wound in two sections in the same way. There are therefore really four windings on the current coil.

Fig. 36 is a diagram of the connections. P is the wattmeter pressure coil. C C is the main current coil. K K is the compensating current coil. The two parts of these coils can be respectively connected in series or parallel by the switches S_3 and S_4. L is the lamp under test and l is the subsidiary lamp which is switched on by the switch S_2 for the purpose already explained, when the lamp L is being changed. R is the variable resistance, and S_1 is the main switch. V is the voltmeter, and A the ammeter. It will be noticed that the voltmeter current, as well as that through the pressure coil of the wattmeter passes through both the windings of the current coil of the wattmeter, and its effect is therefore neutralised.

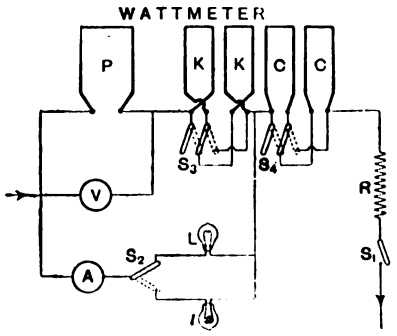

FIG. 36.

If an ammeter is used it may be placed where it is shown in the diagram, provided that it has a resistance extremely small compared with that of the lamp under test. If, however, its resistance is not very small it must be connected so as to take the whole of the current, including that of the voltmeter and the wattmeter pressure coil. In this case it should have a double winding, precisely as the current coil of the wattmeter, so that it indicates only the current through the lamp.

In a wattmeter constructed on the above lines by the author most of the high resistance wire was wound on the suspended coil, which was consequently heavy, and required a vane moving in glycerine in order to damp its oscillations. Mr.

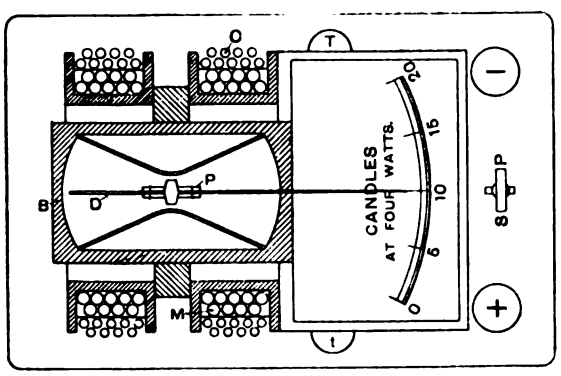

FIG. 37.—Sectional Plan of Evershed's Wattmeter.
(For reference letters *see* Fig. 39.)

Evershed has designed a wattmeter for lamp testing of a more delicate construction, the suspended coil being very much lighter than in the instrument the author has used. By the courtesy of Mr. Evershed the author is able to give the accompanying sketches of the instrument, Figs. 37 and 38. Fig. 39 is a diagram of the connections which are similar to those in Fig. 36. There are two small pressure coils P P., one on each side of an aluminium vane D. This vane fits the vane box B only very loosely, but it is so large and light that the air damps out the oscillations in about two seconds. The bifilar suspension F passes over a pulley at the top. In this way it is ensured that the strain is equally divided. The suspension is silk where it passes over the pulley, but just below the pulley it is wire, and serves to convey the current to the coils P P. Fine wires lead the current to and from the suspension wires at their junction with the silk. In series with the pressure coils P P is a platinoid resistance, R, situated in the base of the instrument. M is the main current coil, and C is the compensating coil for the current through the pressure coil and the voltmeter. T is the terminal of the

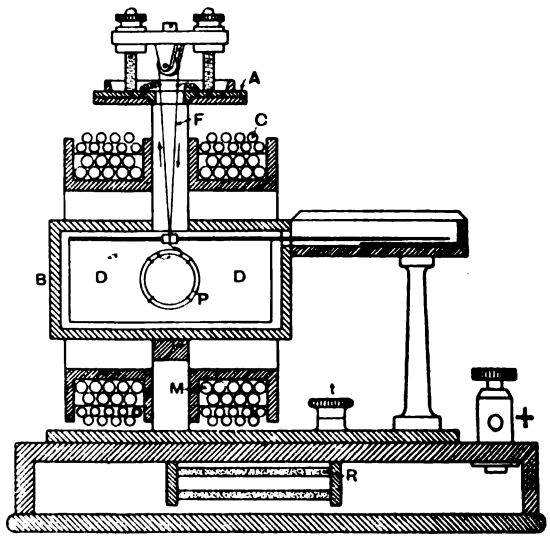

FIG. 38.—Sectional Elevation of Evershed's Wattmeter.
(For reference letters *see* Fig. 39.)

pressure coil circuit, t is the terminal for the voltmeter. The main terminals are marked + and −. A is a plate carrying the pulley, and is capable of rotation for adjusting the zero. S P is a switch for coupling the coils M M and C C respectively in series or in parallel, and so obtaining a double range. V is the voltmeter, and L is the lamp under test. I is the index of the instrument. This arrangement of the index and scale is not good for rapid testing in the manner already described, as the observer at the photometer has to turn away from the photometer in order to read the instrument which must be placed on one side so that he can look down upon it.

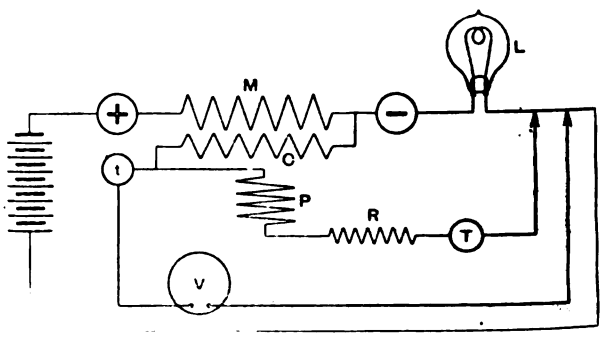

FIG. 39.—Diagram of Connections of Evershed's Wattmeter.

+ −, Main Terminals; T, Terminal of "Pressure" Coil Circuit; t, Terminal for Voltmeter; M, Main "Current" Coils; C, Compensating Coil for Pressure Coil and Voltmeter Current; P, Pressure Coils, in Series with Platinoid Resistance R; D, Vane Box for Damping Oscillations; D, Aluminium Vane to which P P is fixed; F, Bifilar Suspension, serves to lead Current into P P; A, Plate carrying Pulley and capable of Rotation to adjust Zero; I, Index; S P, Switch to couple M M and C C in Series or in Parallel and obtain double range; V, Voltmeter for Measuring Pressure on Lamp Terminals; Lamp under Test.

The method of compensating the wattmeter and ammeter for the error due to the voltmeter current was devised by Mr. Swinburne.

For laboratory testing, where speed is not so important, it is sufficient to test with an ammeter and voltmeter only. The ammeter, if of an appreciable resistance, should be connected so as to measure the current through the lamp, plus the voltmeter current. A table of the voltmeter current for each volt can be hung up in a convenient place, and the amount can be deducted from the ammeter reading at once.

(To be continued.)

MANCHESTER MUNICIPAL ELECTRIC POWER STATION.

The event which took place on Saturday and Sunday, September 23rd and 24th, of the transference of the whole of the lamps on the Manchester electric power mains from the temporary two-wire 100-volt arrangement, on to the regular five-wire 400-volt system, for which the mains and generating machinery have been designed, may be said to mark the point at which this station passed from its incipient stages into the full-grown activity of adult life. Not that the station is as yet completed, for ample allowance has been made in building for that extension of plant which is bound to result from the introduction of electric light and power into so populous and industrial a centre as Manchester city; and the spacious machinery hall is but one-fourth filled, or the extensive space allotted to boilers is as yet only partially roofed over. Nor even that the existing plant is quite fully loaded; although some ten thousand glow lamps were on the mains at the time of the transference to the regular system.

The system of distribution and the generating plant have been constructed to plans designed by Dr. J. Hopkinson, consulting engineer to the Corporation. In general it may be described as the continuous-current, five-wire, direct-feeder system; although ultimately the network of mains may require to be fed at the most distant points by means of continuous-current transformers. The principle of this system is indicated by Fig. 2. The five parallel lines, a, b, c, d, e, represent the distributing mains, between each adjacent pair of which there is a pressure of about 100 volts, to which the house service mains are connected as required, as shown at x and y.

The outermost mains, a and e, are of sufficient section to take the whole load at the 400 volts pressure which is maintained between them, this load being determined by the distance apart of the feeding points. But the inner mains, b, c, d, constitute balancing wires, the purpose of which is to carry the outgoing or return current due merely to the difference of loads on the two sections on either side of them; they are, therefore, of smaller sectional area. This system of five wires, which is carried throughout the entire area supplied with power, is fed at a number of points—the number is eight at present—by means of several pairs of feeders, as at f_1 and f_2, which are supplied with power from large 410-volt dynamos, D. Besides the power derived from these, the mains receive power from the balancing dynamos, 1, 2, 3, 4, which are placed directly on the several sections of the five-wire mains, and are not coupled to the feeders. It is the function of these smaller generators, which are run at the pressure of each section, to balance the load between any two adjacent pair of sections. Since great care is taken so to dispose the load that the difference between the loads on any two sections shall be but a small fraction of the whole load, it will be evident that these balancing dynamos need not be very large. The Manchester mains are partly composed of bare copper strip, supported by porcelain insulators, and set in spacious concrete conduits, and partly of Silvertown

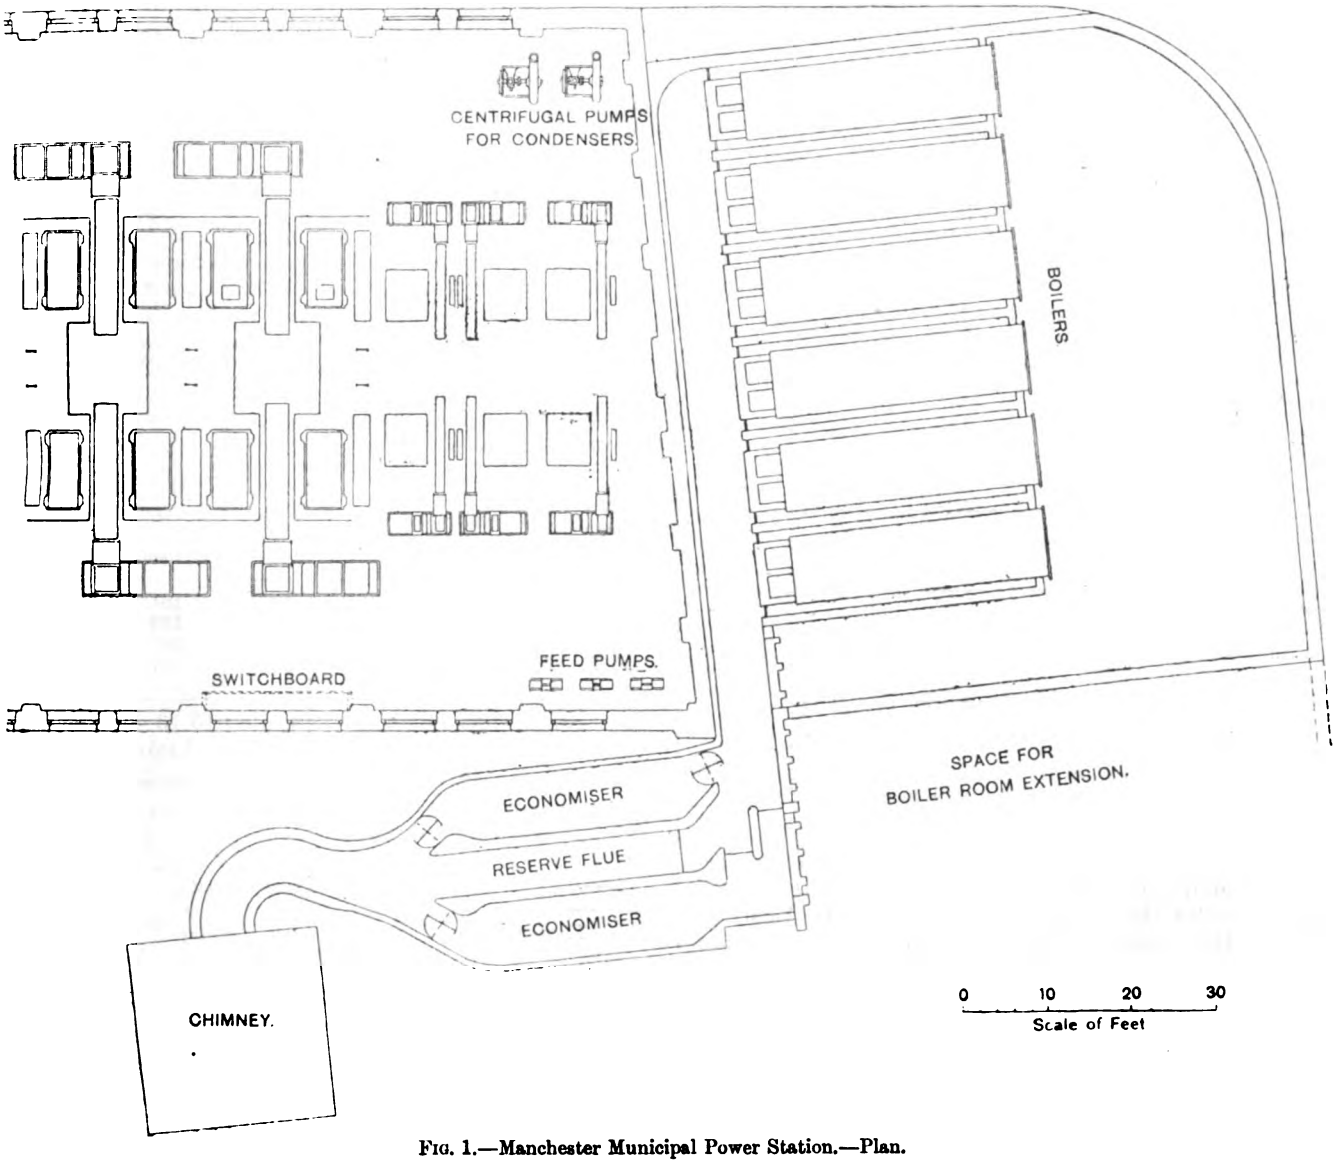

FIG. 1.—Manchester Municipal Power Station.—Plan.

Digitized by Google

covered cable. The former kind of main is at present most commonly used, both for the various feeders and for the five distributors; but flexible covered cable, laid in cast-iron conduits, is entirely used in carrying the current under roadways, owing to the brittle nature of the bare-wire system. This, of course, necessitates a draw-box at each side of every street crossing, which involves a considerable number of main joints per mile run of conduit where the streets are dense. The drawing-in system can only be employed where covered flexible cable is used, and the conduits for the bare strip conductors are placed under the footpath. These latter conduits are provided with a slight fall towards the surface boxes, at each of which they are drained into a well, which is trapped on to the street sewers.

In order to maintain the conduits in as dry a state as possible a draught of air is circulated continuously through them by means of a fan propelled by an electromotor at the station. In the event of any section of the culverts becoming very wet, it is arranged that this ventilating plant can be temporarily removed to the nearest surface box, where it can be clamped into place and run from the bare mains. It should be remarked that, in general, the mains are of bare strip wherever the section exceeds four square inches.

The large dynamos for supplying power through the feeders are designed to run at 400 revolutions per minute, each machine giving 590 amperes at a terminal pressure of 410 volts. Two of these manufactured by the Electric Construction Company on the lines of the well-known Elwell-Parker designs, are now running, and others by this firm are to be erected shortly. Machines of similar output, manufactured by Messrs. Mather and Platt on the Edison-Hopkinson design, are also to be

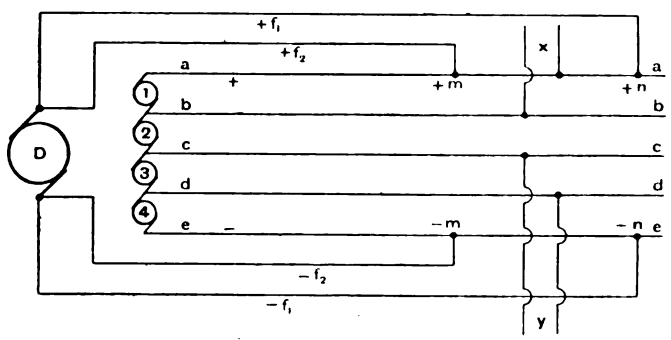

FIG. 2.—Manchester Five-Wire System.

erected, and two of these generators are now running. The engine and dynamo room is designed for 14 of these large dynamos, besides the six smaller distributing or balancing machines. These latter are also Elwell-Parker dynamos, manufactured by the Electric Construction Company, and are designed to give 590 amperes at 102 volts, at 540 revolutions per minute.

The 60-kilowatt machines are of the usual two-pole type, having a single magnetic circuit. They possess an improvement lately introduced into the Elwell-Parker machines which enables the armature to be easily and quickly examined or removed without removing the pedestals and drawing the armature through the magnets. This is attained by cutting the pole pieces in a slanting direction to a height a little above the centre of the armature; these two removal pieces are bolted to a brass grid, and when raised leave half the armature exposed; it can then be easily lifted out in event of an accident. They are fitted at each bearing with patent lubricating pumps. The 240-kilowatt machines are of the double magnetic circuit type, and are also provided with pump lubricators.

One of the stipulations of the contract was that the efficiency of the dynamos should be carefully tested by coupling two similar machines, one acting as motor and one as dynamo, the dynamo restoring the power generated to the motor, the excess required to overcome the losses in the system being supplied by a third machine, the magnetising power being supplied from a separate source. The efficiency was taken as the ratio between the watts generated by the dynamo (measured as its terminals) less the watts required to magnetise, to the watts delivered to the motor plus the watts required to magnetise, or if

D = watts at dynamo terminals,
M = watts at motor terminals,
M_1 and M_2 the watts required to magnetise the dynamo and motor and motor respectively,

then the efficiency = $\frac{D - M_1}{M + M_2}$.

It was decided in the case of the Elwell-Parker machines to couple the machines together by means of belts and sacrifice the loss in the belts rather than make special arrangements for bolting the two armatures together by means of prolonged shafts and special couplings. The 60-kilowatt dynamos were run for six hours. During the last hour readings of the current and voltages were taken. The final result gives an efficiency of 84·5 per cent.; this, of course, included loss in the belt, which was double leather 9in. wide, or an efficiency of each machine of 92 per cent. The armature resistance was 0·00319 ohm when hot, and the field-magnets under similar conditions 9·26 ohms, from which figures it follows that the loss in the armature is the same as that in the F.M. coils, each being 1·85 per cent. of the output. This leaves about 8 per cent. in the combined system to be accounted for by hysteresis, friction, and belt loss; allowing a 2 per cent. loss in the belt, the efficiency of each machine would come to, say, 93 per cent. The 240-kilowatt dynamos were tested in a similar manner, but the difficulties with respect to the belt were greater. There was not one to hand wide enough for the work, so the dynamo was driven by a 16in. double leather belt on the top of which rode a 12in. link belt. The following observations were made during the last half hour of a six-hour run with full load:—

E.M.F. Dynamo.	Excess.	Current.	Speed.	E.M.F. across magnets.	
				Dynamo.	Motor.
419	47·75	590	395	191	225
413	47·75	600	392	189	223
410	46·99	580	387	191	225
407	47·07	600	377	197	237

F. M. coils, motor (four parallel) 15·13 ohms.
F. M. coils, dynamo (four parallel) 14·31 ohms.

The coils were coupled four parallel for convenience of excitation; they run normally two parallel. From the above the following figures are calculated:—

Dynamo.		Motor.		Magnet Kwatts.		Speed.	Effiney.
Volts.	Kwts.	Volts.	Kwts.	Dyn.	Motor.		
419	247·2	466·75	275·3	2·55	3·34	395	87·8
413	247·8	460·75	276·4	2·49	3·28	392	87·7
410	237·8	457·0	265·0	2·55	3·34	387	87·63
407	244·2	454·07	272·4	2·71	3·71	377	87·46

Resistance of armature at end of run, 0·00916 ohm; cable connecting the two machines, 0·00044 ohm. These readings were taken on carefully tested instruments of Lord Kelvin's, the 400-volt reading being measured on an electrostatic voltmeter, and the difference of E.M.F. between motor and dynamo measured on a centi-ampere balance; by this means the efficiency could be arrived at very accurately. Without making any allowance for belt loss, which must have been heavy, the efficiency of one machine is thus 93·7 per cent. The power lost in the magnets and armature is very low, being only 1·06 per cent. in the former and 1·3 per cent. in the latter. These tests were taken under the superintendence of Dr. John Hopkinson, who certified the machines as 84·5 per cent. and 87·7 per cent. combined efficiency respectively. The tests on the Mather and Platt dynamos were arranged to the same specification, but were carried out without the use of belt gearing. They therefore showed a more nearly accurate and better result, giving a combined efficiency of 90·5 per cent., or an efficiency per machine equal to about 95·2 per cent. The

stipulated combined efficiency in all these tests was 83 per cent., and a bonus of £30 per additional 1 per cent. was offered to the contractors.

The six small balancing dynamos are driven by six vertical tandem compound condensing engines, designed and erected by Messrs. R. Hornsby and Sons. These engines work by steam at 120lb. pressure, and are constructed to run at from 120 to 135 revolutions per minute. The high-pressure cylinder is 10½in. diameter, the low-pressure cylinder is 16in. diameter, and the stroke is 2ft., so that the piston speed varies from 480ft. to 540ft. per minute. This variation of speed is necessary on account of the variation of drop on the feeders being regulated entirely by regulation of the engine speed. The regulation is effected through the action of the governors on the cut-off valves, and not by throttle valves. There is a massive bed plate which carries the crankshaft, and on this is a vertical cast-iron frame at the back, and two wrought-iron columns at the front which support the low-pressure cylinder. At the top of the low-pressure cylinder, at a sufficient height to make it easy to get at the glands, the high-pressure cylinder is mounted. The slide of the low-pressure cylinder is on one side of the engine, whilst the high-pressure slides are on the other, the former being adjustable; and the latter consists of two slides, one having an automatic cut-off, which is regulated by the governor. The governor is of a massive description, of the Porter type, and is said to control the speed of the engine in a most efficient manner. The engines are supplied throughout with all the necessary lubricating arrangements so that they can be run continuously. The condenser is one of Ledward's automatic ejector condensers. The power is taken from the fly-wheel by link leather belting, an arrangement of jockey pulleys, enabling the engine and dynamo to be arranged on a very short "centre," thus econo misïng floor space. The large dynamos are driven by a similar arrangement of gearing, by vertical compound condensing Galloways' engines. Each of these engines has a high-pressure cylinder 17in. diameter and a low-pressure cylinder 34in. diameter, both pistons having 3ft. stroke. The cranks are set at right angles, which necessitates the use of a receiver for the steam in its passage from the first to the second cylinder. Both cylinders and the receiver are jacketed with live steam taken direct from the boilers. The speed of the engine varies with the load, and is regulated by Galloways' high-speed parabolic governor, so arranged that the speed of stability can be altered while running. The engines are intended to work at 120lb. steam pressure, and develop 400 I.H.P. at a piston speed of 500ft. per minute. Each engine is fitted with a Körting's ejector condenser, which is supplied with canal water by means of centrifugal pumps driven by separate engines.

The general arrangement of the engines and dynamos is shown in Fig. 3, in which a transverse vertical section of the station is given. This shows the jockey pulleys on the larger machines. The distance between centres in these machines is 11ft. 4in. between engine and jockey pulley, and 5ft. between jockey pulley and dynamo. The diameters of these pulleys are: Engine 16ft., jockey pulley 3ft., and dynamo 2ft. 3in. It might be supposed that the use of jockey pulleys with such large pulleys on these very short centres would cause a severe and wasteful thrust on the jockey pulleys; but, as a matter of fact, this does not appear to be the case. The jockey pulley is, of course, placed on the slack side of the belt, with the result that when the load is very large the belt sags below the jockey pulley surface, and gives a sufficient arc of contact on the driving pulleys without it.

The boilers are of the horizontal, cylindrical, twin-flue type, known as the Lancashire boiler, and are fitted in each internal flue with four Galloways cross tubes. They have been manufactured by Messrs. Galloways and Sons, and are intended to work at 125lb. steam pressure. Each boiler is 30ft. long and 8ft. diameter, and is provided with all necessary fittings, many of these in duplicate, and with a Vicars' mechanical stoker. The boiler arrangements and housing are shown in Fig. 5.

The boiler-house when complete will be provided with twelve of these boilers. Each boiler is automatically supplied with fuel, the coal being fed into the hoppers of the stokers from a traveller which runs along a platform over the end of the boiler-house. This platform terminates immediately over the side of the Manchester and Rochdale canal, the proximity of which affords great convenience for coaling and for the supply of condensing water. Water for the boilers is taken from the city supply, and is stored in capacious tanks, placed over a portion of the boiler-house, having a capacity of 200,000gals. The main steam pipes are of wrought steel, 18in. bore, welded, with strips double rivetted over the weld, and are duplicated throughout. They are supplied with steam from two separate stand-pipes on each boiler, and all the cocks and valves are in duplicate. The feed pipes, which are also in duplicate, are 5in. in bore, and supply the boilers with water which has been previously heated by one of Green's well-known furnace economisers. Air is supplied to the furnaces by natural draught produced by an octagonal chimney 212ft. high. The chimney foundation is 34ft. square, and the diameter of the chimney at the top is 11ft. 10in., about 1¾in. of water of draught being produced.

Having now described the general arrangements for generating power, it will be instructive to consider more particularly some of the details. The switchboard is of novel and ingenious design, and appears to be both well adapted to its present purpose and capable of ready extension without confusion

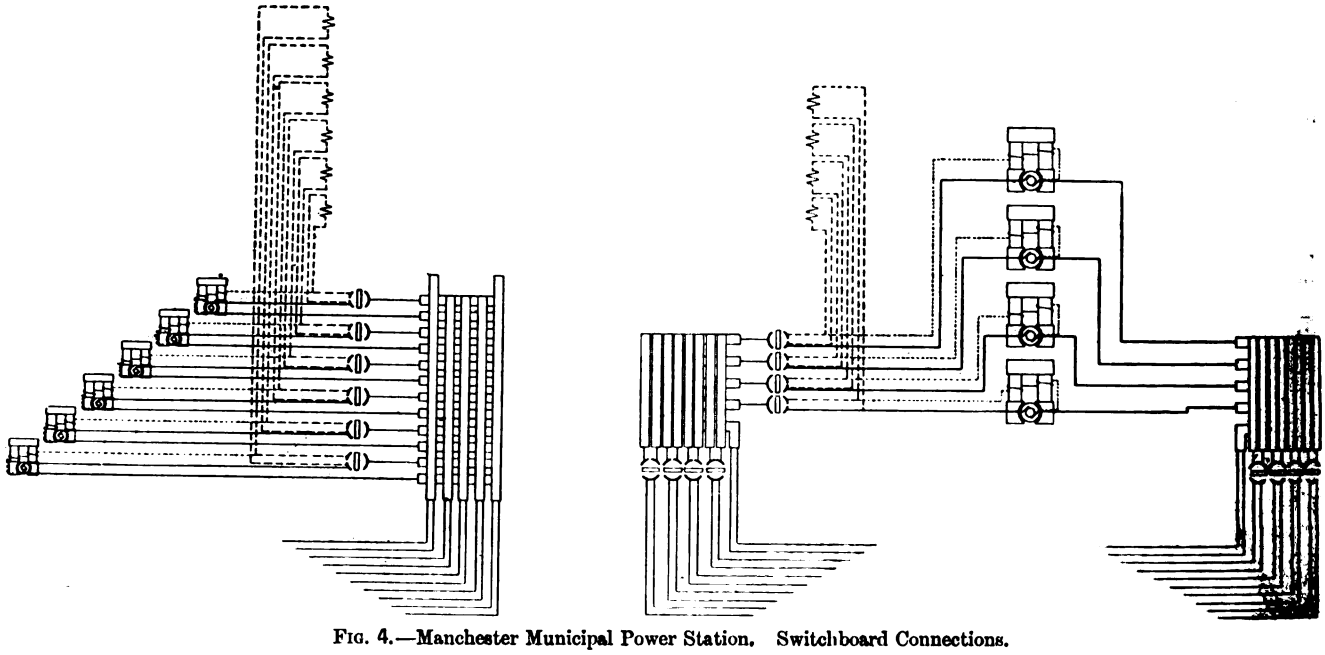

Fig. 4.—Manchester Municipal Power Station. Switchboard Connections.

Mr. Crompton's resistance is a rectangular sheet of manganin, and the potential terminals are two screws inserted at a suitable distance apart in the median line. The screws are not soldered. I thought it would be of interest to unscrew them, then screw them up again, and remeasure the resistance. The results were :—

August 10th (morning)	0·00050328
August 10th (afternoon).....	0·00050322
August 10th (afternoon).....	0·00050327
Mean	0·00050326

a variation of about 1 part in 500.

I unscrewed them again, and after screwing them up once more remeasured, with the following results :—

August 11th (morning)	0·00050398
August 12th (morning)	0·00050403
Mean	0·00050401

which, compared with the first value, 0·00050222, gives a variation of, roughly, one part in 280.

The conclusion is that if an accuracy of one-tenth per cent. is desired the potential terminals ought not to be meddled with after the resistance has been determined.

In making these measurements my direct object has been to obtain an accurate and ready method of measuring these low resistances. But I think something more than this comes out of them.

It would be possible, in the light of our present experience, to construct a Lorenz apparatus considerably more accurate and easier to use than the one in my laboratory at Cardiff. Such an apparatus placed in the National Laboratory, of which we have heard a good deal at recent meetings of the British Association, might with advantage be kept in constant use, not only for the calibration of low resistances, but also as embodying in concrete form a proper ultimate standard of electrical resistance. We have not, in our electrical standard legislation, given full credit to the mechanical engineer for what he can do for us ; and I think that a coefficient of mutual induction, arranged as in the Lorenz method so as to be easily combined with a time, would afford a more satisfactory standard of resistance than any wire coil or coils, and one easier to use, for purposes of ultimate reference than any mercury column.

ON THE MAXIMUM EFFICIENCY OF ARC LAMPS WITH CONSTANT WATTS.*

BY PROF. H. S. CARHART.

It is of interest to determine, in connection with the proposal to define a 2,000-c.p. arc light in terms of the watts expended on it, whether the illumination is independent of the current as a variable. If a 2,000-c.p. lamp shall be defined as one requiring 450 watts for its maintenance, shall the current be 10 amperes and the potential difference of the arc 45 volts, or will a smaller current and a higher voltage give higher illumination ?

The present Paper can be considered as describing only a single step toward the solution of the problem, or a preliminary note relating to experiments conducted under one set of conditions. It seems quite clear that with any definite number of watts the candle-power will be a function of the current, the size and quality of the carbons, and perhaps also of the source of the current, whether from a constant potential circuit or from an open or a closed coil constant-current machine. The experiments conducted by three of my pupils, Messrs. Raymond, Hookway and Fisher, have been confined to the circuit of a constant-current dynamo with closed coil armature, and to soft plain carbons $\frac{7}{16}$ths of an inch in diameter, made by the Standard Carbon Company, of Cleveland.

The method employed was as follows :—With any constant current within limits a series of measurements of candle-power was made by changing the length of the arc and hence its potential difference. A curve was then plotted with candle-power and volts as co-ordinates. Fifteen such curves were drawn for currents ranging between 6·75 and 10·75 amperes. Then any number of watts were chosen, say 450, and this was divided in succession by the several currents used in obtaining data for the fifteen curves, or by so many of them as came within practical limits. With the potential differences obtained in this manner, and the corresponding candle-powers read off from the several curves, another curve was constructed, with candle-power and volts as co ordinates and with the watts constant. Such curves show a maximum point corresponding to the volts at which the lamp gives the greatest candle-power. The measurements were all made in the photometric room with a 32-c.p. incandescent lamp as a standard of comparison. The arc lamp was mounted so that the arc was at the extremity of a radius of half a metre, movable about an axis parallel to the photometer bar. The end of this axis carried a plate-glass mirror from which the light of the arc was reflected down along the bar to the photometer box. The arc or its image in the mirror was thus kept at a fixed distance from the incandescent lamp, and its position was always such that the light came from the arc at an elevation of 45deg. The absorption of the mirror was measured and found to be 8·7 per cent.

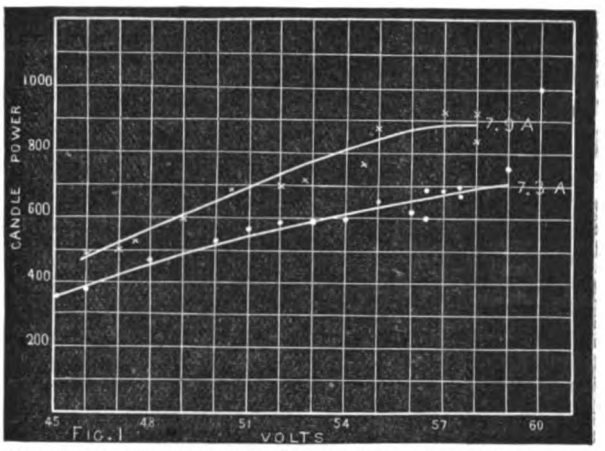

FIG. 1.—Candle-power and volts with 7·3 amps. and 7·3 amps.

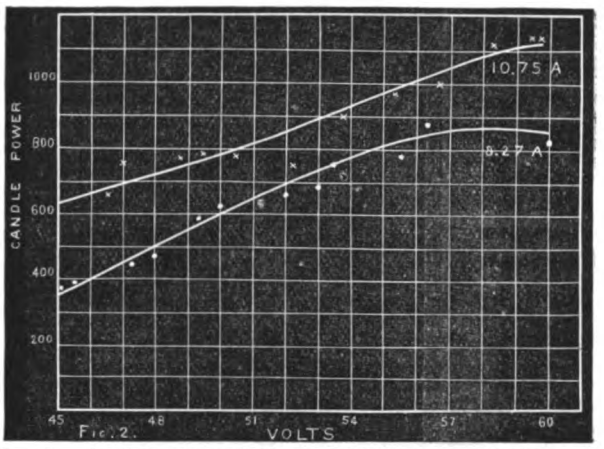

FIG. 2.—Candle-power and volts with 10·75 amps. and 8·27 amps.

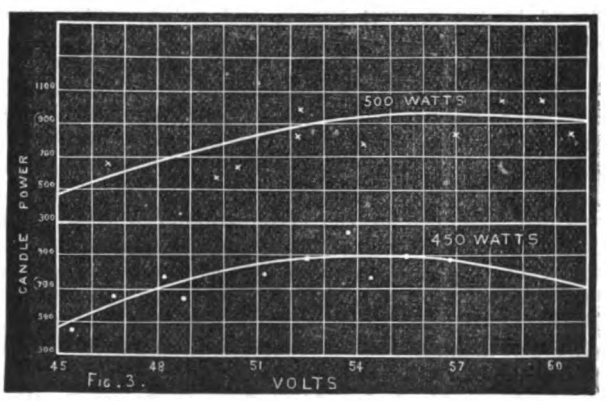

FIG. 3.—Candle-power and volts at 500 watts and 450 watts.

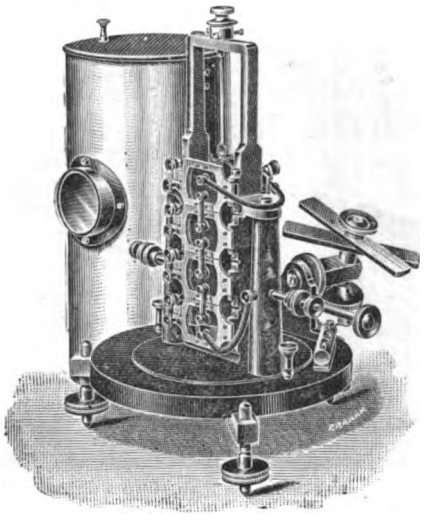
* A Paper read before the Electrical Congress, Chicago.

Digitized by Google

I have plotted only four of the fifteen curves composing the series. Fig. 1 contains two curves with currents of 7·3 and 7·9 amperes, and Fig. 2 two others at 8·27 and 10·75 amperes respectively. It will be seen that a maximum of only a little over 1,100 candles was obtained. Fig. 3 contains the two curves derived from all the data, and with constants of 450 and 500 watts respectively. Both show a pretty well defined maximum at about 54 and 55 volts respectively. Hence for a lamp of 450 watts the current should be about 8·4 amperes with the carbons described above. The candle-power was then 900. At 10 amperes and 45 volts this curve shows the surprising fact that candle-power was only 450. With 500 watts the current rises to about 9 amperes and the voltage to 55. I attach no great importance to these particular figures, but the series of experiments shows a very large variation of candle-power, current and potential difference varying inversely, their product or the watts remaining constant. It is proposed to extend the investigation to other carbons of different size and quality, and to currents of an open-coil machine; but enough has already been done to show that the definition of a 2,000-c.p. lamp as one on which 450 or 500 watts are expended is not so definitive or unobjectionable as might at first be supposed.

A SENSITIVE BALLISTIC GALVANOMETER.

Dr. Oliver Lodge described a new galvanometer for physiological purposes before Section A of the British Association at Nottingham. It was designed by himself and made by Messrs. Nalder Brothers. The nerve currents excited by stimuli



are exceedingly feeble, and, even with the so-called non-polarisable electrodes, the currents under investigation are frequently masked by other effects. Physiologists require an exceedingly sensitive ballistic galvanometer; but they appear generally to use needles which are far too heavy, in the endeavour to get a long period, and galvanometers which are too highly damped, and which manifestly cannot be so delicate as undamped galvanometers. The best form of galvanometer for their requirements is one which contains a very light needle built up of short pieces of highly magnetised steel wire and in which the coils are small, and are wound up as close as possible to the needles. The moving parts should be as small as possible to avoid damping. The instrument, which is shown in the accompanying illustration, has four such coils and four needles, forming an astatic system suspended by a quartz fibre in a very weak field. Compared with the usual galvanometers of the same resistance, its sensitiveness is at least twice as great. Prof. Boys has shown that excellent definition can be obtained from a small scrap of reflecting mirror; and Lord Rayleigh has shown that a pointer read by a microscope admits of just the same degree of delicacy as the mirror method. As biologists are accustomed to looking through microscopes, Dr. Lodge suggests that they might prefer to observe through a micrometer eyepiece a needle with a bee-sting as pointer, and thus avoid the weight of the mirror.

LAMP TESTS AT THE WORLD'S FAIR.

Prof. B. F. Thomas, Chairman of the Sub-Committee (4) of the Committee on Awards, has given out the following authoritative statement as regards the testing of incandescent lamps at the World's Fair. The lamps entered in the test are as follows:—

Edison lamp, 50 volts and 110 volts, and Thomson-Houston lamp, 50 and 110 volts, entered by the General Electric Company.

Novak lamp, 50 volts and 110 volts, by the Waring Electric Company.

Packard lamp, 50 volts and 110 volts, by the New York and Ohio Company.

Stopper lamp, 50 volts, by the Westinghouse Electric and Manufacturing Company.

The number of lamps of each make is limited to 40 of each voltage, or 80 of each make, except the "stopper" lamp of the Westinghouse Company, which enters simply as a 50-volt lamp.

The manner of testing that has been decided on by the Committee, and agreed to by the competitors, is as follows:—

Lamps entered for award shall be subjected to a test whose object shall be to determine the mean horizontal candle-power, the efficiency and life, and the blackening of the lamps entered at proper intervals during the time covered by the test.

Current Supply.—The Fort Wayne Electric Company has placed an engine and all dynamo machinery necessary at the disposal of the Committee; 110-volt lamps will be supplied with direct current and 50-volt lamps with alternating. Lamps will be placed on racks, on circuits of heavy copper rod, all lamps of a given voltage being on one circuit. Careful provision will be made to maintain voltage constant.

Standards.—The English sperm candle for candle-power. Electrical standards as agreed upon by the Sub-Committee on instruments.

Instruments.—For candle-power measurements, a Lummer-Brodhun photometer, length of bar, 250cms., Methven screen, using carburetted gas—gas to be filled with gasoline distilled between 35° and 50°C. The electrical instruments used will be Weston instruments, which will be tested at the beginning of the test, and at intervals during its progress by Sub-Committee (1) on instruments, &c. Recording voltmeters (if such can be obtained) will be placed on the life test circuits.

Scheme of Test.—The photometer being properly mounted, the Methven screen will be tested by comparison with standard candles. This test being satisfactorily completed, two or more 32-c.p. lamps, of proper voltage carefully selected with reference to uniformity of radiation in a given direction, will be tested at standard voltage. One of these lamps, so measured, and thereafter designated as working standard, will be placed on the photometer. Each lamp entered for test will then be compared with the working standard, both being carefully adjusted to standard potential. The mean horizontal intensity of each lamp will be obtained, preferably by spinning, when under comparison with the working standard, which latter will be maintained at about 16-c.p. The candle-power of each lamp in a marked position (azimuth) will also be determined at the same time, and its "position factor" derived. At the same time that the photometric work is done on each lamp careful reading of potential and current, or of potential and watts, will be taken. A storage battery will furnish current to all lamps when under photometric tests. At intervals (as small as convenient in the earlier days of the life test) each lamp will be removed from the test rack, placed on the photometer in its "marked position," and readings of candle-power, voltage and current (or watts) taken.

Results.—The data of the test will be completed and tabulated, and curves will be drawn so as to show the following points:—

(1) Mean horizontal candle-power, and percentage of initial candle-power, at each reading throughout the test.

(2) Efficiency (watts per candle-power) at each reading.

(3) Time of breaking of each lamp broken.

(4) Average cost of a candle-power hour of light produced by each make of lamp at intervals during its life, such cost to include cost of lamp and cost of energy required to operate it. Separate curves will be prepared for the average of each make, giving the above cost under varying conditions, varying from 15 to 50 cents for cost of lamp, and from 10 to 25 cents for cost of 1,000 watt-hours of energy.

Report.—A report upon the test, giving a full account of all points concerning the methods and instruments used, details of machinery and circuits, all original readings, &c., will be formally made to the proper official of the Exposition, with the recommendation that it be printed at the earliest possible date. The test will continue until October 1st, running 24 hours per day, and if at that time it seems desirable to continue the run, the committee will endeavour to secure such continuance. With the exception of "spinning," the above scheme is acceptable.

THE CERTIFICATION OF THE HEFNER LAMP.*

The German Reichsanstalt has recently communicated to the papers some details, which are of importance to all those interested in the question of light standards, on the subject of the preparation and construction of the Hefner lamp, and the conditions which must be observed in order to ensure uniformity in its indications. As is well known to all who take an interest in this matter, it was in 1884 the Herr von Hefner-Alteneck first proposed a system of measuring the intensity of illumination by means of a unit, which he defined as follows :—"As unit of light shall be used that illuminating power which is possessed by a flame rising from a massive wick saturated with amyl acetate, and burning freely in pure, still air. The wick is to completely fill a german silver tube of 8mm. inner, and 8·3mm. outer diameter, and 25mm. clear length, and the flame shall be 40mm. high from the summit of the tube, measured not less than ten minutes after lighting the lamp." The intention of the Reichsanstalt to take up the question of the Hefner unit was greatly strengthened when, in 1890, the German Gas and Water Union, with the purpose of introducing the Hefner unit into gas work, applied to the Reichsanstalt to consider the question of issuing certificates for this form of lamp.

Preliminary experiments gave, on the whole, a result very favourable to the Hefner lamp. It was found that a very considerable degree of accuracy was unnecessary in the above dimensions, and the only important point appears to be the thickness of the sides of the wick tube, the illuminating power being diminished if the tube is too thick, while if it is too thin the flame does not burn steadily. A great degree of purity is necessary also in the amyl acetate, and simple means can be applied to detect excessive impurity ; and, in addition, the acetate is not affected by keeping. On the other hand, it is necessary to properly ventilate the lamp, as the pressure of carbondioxide has a very appreciable effect in diminishing the light ; there are also small variations due to meteorological conditions, but these are not large enough to affect practical work. Other small difficulties are due to unsteadiness in the flame, and the want of definite limits to measure the height by, but the great superiority of the Hefner lamp to other suggested units caused the Reichsanstalt to support strongly its adoption.

At the same time, the question of form was being discussed with the maker, and it was determined to adhere to the original specification. Every lamp to be certified should have a "flame-measurer" for determining the height, and an appliance for controlling the position of the flame-measurer above the upper side of the wick tube, and all lamps were to be to a standard pattern. As flame-measurer, the simplest forms were adopted, the Hefner-Alteneck eyepiece and the so-called "optical flame measurer" of Dr. Krüss. As far as the experiments at the Reichsanstalt go, two lamps, precisely similar in dimensions, burning in similar air, give within limits of observation precisely the same amount of light, that is to say, that a test of the Hefner lamp need only include proper measurements of its dimensions, but it has been considered as well also to measure the light photometrically, and to add the result to the certificate, in order to collect as much information as possible on the subject. It seems probable that even if the time has not arrived to make it a legal unit, the Hefner light will shortly displace the "standard candle" in Germany, as it has already for some years in the laboratories of the Reichsanstalt, and it will therefore be necessary to determine the ratio of the old and new units. The two old units most in vogue in Germany are the so-called English standard candle (flame 45mm. high) and the German Union Paraffin candle (flame 50mm.). The former gives a mean value of 1·41 Hefner light, and the latter 1·2.

The remainder of the report contains specimen certificates, instructions, tariff, and a description of the standard Hefner lamp.

IRON FOR TRANSFORMERS.†

BY PROF. J. A. EWING, F.R.S.

In selecting iron for use in the core of a transformer the first consideration is smallness of hysteresis losses ; high permeability is comparatively a secondary desideratum. These two good qualities do not necessarily go together ; the curve of the B-H cycle may have a relatively easy slope, and yet enclose a relatively small area. In actual tests the author has noticed that the order of merit in a set of samples is not always the same if permeability be made the criterion, as it is if smallness of hysteresis losses be the criterion.

Notwithstanding the obvious and well-recognised importance of small hysteresis losses in transformer iron, the metal that is actually used is often of a very poor quality in this respect. The author has been much struck by this in the course of a recent experimental inquiry in which ten or a dozen specimens of iron were examined, most of which were supplied either as transformer iron or as specially pure metal prepared for the purpose of the experiment. In only one case were the hysteresis losses as low as they had been found to be in some wire which the author tested in 1881, in the laboratory in the University of Tokyo, and in most cases the losses were much greater. In the Japanese tests which were made before the days of alternating-current engineering, when the word hysteresis was to be found nowhere but in the Greek dictionary, wires were taken at random from the stock which the laboratory chanced to furnish. Two of them were about equally good ; one of them was probably a piece of native iron, and the other was wire sent by an American manufacturer to an exhibition in Japan. Since then many observers have made tests, and, obtaining decidedly inferior results, have not unnaturally been led to express themselves in terms of politely veiled scepticism about the Japanese figures. It is therefore interesting to notice that one sample among those most recently tested by the author has given results which are substantially on a par with those given by the Japanese wires. Under strong magnetisation it is not quite so good, but when the magnetisation is moderate or weak there is practically no difference. The sample in question was thin sheet iron, used by a well-known English firm in the building of their transformers. But the corporation of the old figures, interesting as it is, only serves to emphasise the contrast between the good and the bad. Other iron, also used by eminent makers of transformers, and also, like the last, carefully annealed before testing, turned out so markedly inferior that the author does not care to indicate the sources of his specimens by any more particular description. And the case was even worse with some iron supplied as specially soft and pure.

The following figures may be given as representative :—They give the value of S H d I, or the hysteresis loss incurred in a complete cycle of magnetic reversal, for various values of the magnetic induction B which is reversed. Column 1 states the results of one of the old Japanese tests, column 2 refers to the good sheet iron mentioned above, and column 3 refers to another specimen of transformer metal, where, it will be seen, the losses are about half as great again as in the other. Column 4, where the losses are much greater still, relates to a test of some wire which was furnished as a specimen of particularly fine Swedish charcoal iron.

Table of Hysteresis Losses.

B.	Values of S H d I.			
	1.	2.	3.	4.
2,000	400	420	600	1,100
3,000	780	800	1,150	2,150
4,000	1,200	1,260	1.780	3,300
5,000	1,680	1,770	2,640	4,700
6,000	2,200	2,370	3,360	6,200
7,000	2,800	3,150	4,300	7,800
8,000	3,430	3,940	5,300	9,500
9,000	4,160	4,800	6,380	11,400
10,000	4,920	5,730	7,520	13,400
11,000	5,800	6,800	8,750	15,600
12,000	6,700	8,000	10,070	...

The figures given by Mr. C. P. Steinmetz in his Paper on "The Law of Hysteresis" (American Institute of Electrical Engineers, 1892) give additional evidence of the wide variation which this quality is liable to exhibit in different specimens of nominally soft iron.

Chemical analysis is apparently an imperfect guide in the estimation of magnetic quality, and to some extent this is intelligible enough. Puddled iron, for instance, liberally streaked with slag, may seem on analysis less pure than specimens of ingot metal which have much higher hysteresis losses. It is not improbable that much of the inferiority which most modern sheet and wire iron undoubtedly shows in this respect may be due to traces of foreign elements which have become chemically incorporated with the metal through the use of methods of manufacture which are ill adapted to yield a good product from the magnetic point of view, however successful they are in producing a mechanically good iron. Manganese, so essential to the strength and toughness of ingot iron, is well known to be deleterious magnetically. The makers of transformers complain that they are unable to get metal of the quality they want except by a kind of happy accident : that the conditions which bring about a good result are so imperfectly understood that they cannot be reproduced with any certainty. Much the same thing was true in the early days of mild steel, and incessant testing contributed to put matters on a surer footing. Magnetic testing is now easy for makers as well as users of iron, and it may be expected that specifications of magnetic quality, and particularly of hysteresis losses, will soon become commoner than they are. From being a mere laboratory affair, interesting only to the curious physicist, the subject has in a few years advanced to the front rank of practical questions, and affects wide commercial interests.

* Abstract from the *Zeitschrift für Instrumentenkunde*, No. 7, 1893.

† A Paper read before the Electrical Congress at Chicago.

Digitized by Google

The form and general design of transformers has received all possible attention at the hands of engineers, but of the material which mainly determines their efficiency we apparently know very little. It is scarcely satisfactory to reflect that good makers are turning out machines which waste twice as much power as they need waste.

The author brings these remarks before the Congress in the hope that some suggestions may be made which will lead to a better understanding, as between electricians and iron makers, of the conditions which govern the production of magnetically soft iron.

SOME MEASUREMENTS OF THE TEMPERATURE VARIATION IN THE ELECTRICAL RESISTANCE OF A SAMPLE OF COPPER.*

BY A. E. KENNELLY AND REGINALD A. FESSENDEN.

In this Paper, which is of the greatest value in its bearing on laboratory and other work of high precision, the authors first discuss the results obtained by Drs. Matthiessen and Siemens in their classical determinations of the temperature coefficients of copper, and find that they are discordant. The work of other physicists in the same line is also referred to, and the final results of their own determination then resumed in the statement that "they indicate a linear relation between the resistance and temperature of the wire between the limits of 20°C. and 250°C. represented by the equation

$$R_t = R_0 (1 + 0{\cdot}00406\, t),$$

indicating a uniform temperature coefficient of 0·406 per cent. per degree Centigrade throughout that range, the maximum observed being 0·4097 per cent. and the minimum 0·399 per cent. at any point.

Concerning the conclusions that may be drawn, they feel only justified in saying that copper can be found in which a linear relationship holds between resistance and temperature between 20°C. and 250°C., and within the range of small observation errors. It is, of course, possible, they state, that in different samples of wire the temperature coefficient may increase or diminish with the temperature; in other words, the second differential coefficient of resistance, with respect to temperature, may perhaps, in some samples, be either positive or negative. It therefore seems desirable that fresh measurements should be made, and evidence collected to settle this point, and they submit the view that the best experimental means of measuring the temperature and insuring the coincidence between the measured temperature and that of the tested wire, is to enclose the latter in a bulb of an air thermometer in the manner employed in this investigation.

An account of the elaborate measurements is given in great detail in an appendix, not only to support the statements made concerning them, but also because the experimental arrangements of apparatus finally successful were the outcome of a series of experimental failures, and the details of construction may, therefore, be of service to those who desire to adopt the same method of measurement.

An interesting note accompanies the Paper, giving the result of some measurements made on the resistance of copper wires enclosed in exhausted glass tubes, and gradually raised to just visible red heat by gradually increasing the current through them. Assuming the linear temperature coefficient above determined throughout the entire range of temperature, the temperature corresponding to the lowest visible luminosity becomes 493°C. (921°F.). It was found that repeated tests with the same wire and the same observer will usually fall within 2°C. by resistance valuation. There was, however, a systematic variation between the observations when the observers were exchanged of about 3°C.

DISCUSSION.

Mr. PREECE stated that he would like, before the discussion was closed, to be allowed, as a representative from the other side of the water, to express not only their obligations, but their admiration for the manner in which Mr. Kennelly and his co-labourers are attacking this question. Personally he felt a very great interest in it, because it is a subject that he had himself attacked, and he only gave up the further study of the subject when he found that younger and abler men were taking it up on this side of the water. He wanted to point out to Mr. Kennelly that at Cambridge, where the question has been also carefully considered, the discrepancy between the curves of Matthiessen and Siemens, and also the discrepancy that is to be found in the text books and in papers generally as to the specific resistance of copper, is attributable to a difference of density. It has been found by reference to Matthiessen's original Papers that he used copper having a density of 9. At Cambridge they had been using copper which had a density of 8·946, and it was found that with the copper at this density the difference in the specific resistance formed a direct ratio between these two numbers. The numbers, he stated, happened, curiously enough, to be among his papers in a note that he took when Mr. Fitzpatrick read a Paper on the matter at one of the meetings of the British Association, he thought it was at Edinburgh, and the figure there given was for copper at 8·946 specific gravity and 18°C., 1·754; for copper at 8·9 density and the same temperature, 1·766. He remembered after that working that down with a coefficient, the coefficient then given for temperature, and he thought that if Mr. Kennelly would be kind enough to take that note and apply it to the formulas derived from his experiments with his revised coefficient, that we shall find that there will not be much discrepancy between the figure used in England and that used here. On the other hand, we shall be delighted to feel that we have a coefficient derived from the unique means that Mr. Kennelly has in his possession. And Mr. Preece assured him, as a representative of English electricians, that the result of his Paper will be accepted without the slightest hesitation.

* Abstract of Paper read before the Electrical Congress at Chicago.

AN ELECTRIC STREET RAILWAY CONDUIT TRIAL.

In a recent number of the *Electrical World* is an illustrated description of an interesting experimental conduit electric railway at Coney Island, one of the principal features of which is that the line is entirely insulated except when delivering current to a shoe projecting into the conduit from the car. Briefly stated, the system consists of a shoe projecting from the bottom of a car into a conduit, and a series of contact boxes connected with the line and placed at equal intervals along the sides of the interior of the conduit. Levers projecting from the boxes are moved when the shoe encounters them, which switches on the current from the line; the current then passes through the end of the lever by sliding contact on the metallic side of the shoe, and thence to the motor, whence it goes to the return line by the other side of the shoe in a similar manner. The line is completely insulated in the boxes within the boxes, except in those opposite the shoe, which are never more than three in number; as a consequence, any leakage can only occur during the brief time they are connected with the line, and this is provided for by careful insulation of the lever mechanism. A public experiment was made on Friday, September 15th, to show the quality of the insulation of the line under the most adverse circumstances. To this end about 100ft. of the conduit was filled with a mixture of mud and water, and the car was run back and forth, and stopped while readings of instruments were taken to determine if there was any leakage. The measurements showed that practically no part of the current was lost, and those in attendance pronounced the experiment as satisfactory and proving the claims made.

UNION OF THE ELECTRICAL ENGINEERS OF GERMANY.

The first annual meeting of the Union of the Electrical Engineers of Germany was held at Cologne from September 27th to 30th inclusive, when there was a large attendance of members. The evening of the first day of the proceedings was devoted to the reception of the visitors by the Cologne Electrotechnical Society, and on the following morning, by which time there had been many additional arrivals, a meeting was held, at which the President of the Union, Dr. Slaby, occupied the chair. After referring to the objects of the Union, he laid stress on the fact that it was important that the electrical trade should have freedom to develop, and for this the members should strive diligently. After some complimentary speeches had been made, the first annual report was read by Herr Sluzewski, from which it appeared that the membership of the Union had grown from 34 at the time of its formation last January, to 762. The meeting re-elected Dr. Slaby to the Presidency, while Herr Wilhelm von Siemens and Herr Rathenau were chosen as Vice-Presidents. A council of 30 was also appointed. It was agreed to hold next year's annual meeting at Leipzig, and it was also arranged that the members would take part in the Berlin Exhibition of 1896. Herr Pollak read a Paper on the subject of charging accumulators by alternating currents. He considered it often advisable to transform the alternating current transmitted from the generating station into a continuous current, using the latter for charging accumulators and driving direct-current motors. Little success had been met with in the past in this direction, but he had constructed a direct-current converter, of which the efficiency obtained averaged 98 per cent. The author believed that his system would be found of much value in connection with electrical tramway and railway working. The current could then be transmitted at high pressure, and then transformed down and converted into a continuous current. His apparatus could also be used for changing continuous into alternating currents. The system was afterwards shown at work. Herr Ross next read a Paper on the Thomson electric welding system, of which a practical demonstration was subsequently given. The proceedings of the Electrical Congress at Chicago were dealt with by Dr. Budde, who drew special attention to the official fixing of the units.

On September 29th Herr Ross gave a description of the Lagrange and Hoho electrical method of raising metals to a white heat and

Digitized by Google

welding heat, and it was pointed out that by this process even platinum and iridium could be dealt with. The process was also shown in operation at Herr Gottfried Hagen's accumulator works at Kalk. Dr. Kallmann next read a Paper on a Measurement System for Central Stations. Herr Voigt proposed that a committee should be formed to go into the question of arranging a standard for contacts and screws employed in switches, safety apparatus, &c. This proposal was agreed to, and the committee will report next year. Dr. C. Heim spoke on the subject of a portable apparatus for testing the insulation resistance of non-conducting material covering electric conductors and used for their supports. The apparatus is carried in a box, and consists of a delicate galvanometer with two shunts to diminish the sensitiveness by from a tenth to a hundredth, and having a resistance gauge of 10,000 ohms. There is also a dry cell battery, and the current from this can be regulated. Dr. Heim stated that this appliance enabled him to determine insulation resistances from 30,000,000 ohms down to 1,000 ohms. The gathering subsequently devoted itself to visits to works and various festivities, bringing the first annual meeting of the Union to a successful conclusion.

ELECTRIC SUPPLY IN CENTRAL QUEENSLAND.

The Rockhampton Gas and Coke Company's Central Electrical Supply Station was put down under Act of Parliament, under condition that electricity for public and private purposes must be supplied by them within five years. The plant, which was started in September, 1892, consists of two 120 H.P. Root's boilers, by Conrad, Knap and Co., Lincoln; a 100 I.H.P. horizontal engine, by Davey, Paxman and Co.; a 6½in. by 6in. Westinghouse engine; a 280-ampere 110-volt Hookham patent dynamo, with constant lead brush gear, hand regulated by resistances in the field circuit; and an A7 Mordey Victoria alternator. The whole plant is thus capable at present of supplying 2,000 8-c.p. lamps, of which 914 are already in use and 1,700 on order. The Fitzroy Bridge is lighted by alternate-current arcs, and the cathedral by 8 arcs and 20 incandescents. The whole of the mains are laid underground on the Callender system, and the current is charged by Hookham's meter, or by contract, as the case demands. The supply is from 4 p.m. to 7 a.m., and is maintained well. The Company are also contractors for isolated plants, their largest at the present time being the re-establishment of the electric light plant at the Mount Morgan Gold Mining Company's works, Mount Morgan. The whole of the old Weston system has been thrown out, having broken down entirely. Their new plant consists of a 60-light and a 25-light 10-ampere Kapp dynamo with Brockie-Pell arc lamps in series, and a Crompton 100-light dynamo for incandescent lamps. The circuits are over eight miles in length, overhead on poles, and Johnson and Phillips' patent fluid insulators are used. The engine is a 20in. coupled high-pressure Fowler (of Leeds) and two Paxman Lancashire boilers. Over 50 arcs and 30 series Bernstein lamps are in use on the high-tension circuits, and 85 incandescence of 16 c.p. on the Crompton. These two plants are the largest in Queensland, and have been planned and erected under the superintendence of Mr. A. E. Neal.

ELECTRIC LIGHTING AT THE GARDENING AND FORESTRY EXHIBITION.

We have received from Mr. G. C. Fricker the following particulars of the electric light plant for the above Exhibition and grounds, including Capt. Boyton's Water Show and the model Eddystone lighthouse. It comprises almost every practical system of lighting by electricity, viz., high-pressure series arc lighting, low-pressure parallel arc lighting, alternate-current arc lighting with transformers, high-pressure alternate-current incandescent lighting with transformers, and direct-current electric motors and alternate-current electric motors, besides the special arrangements required for the automatic luminous fountain and the ornamental coloured lights in the trees on the lawn of the Welcome Club.

The steam generating plant in the main engine-room consists of four steel locomotive boilers by Messrs. Davey, Paxman and Co., each capable of evaporating about 300 gallons of water per hour, and working at a pressure of 120lb. per sq. in.; one compound horizontal fixed engine, capable of working up to 210 I.H.P.; one compound horizontal fixed engine, capable of working up to 120 I.H.P.; and one coupled compound engine of the girder type, capable of working up to 120 I.H.P.

These latter, which are also by Messrs. Davey, Paxman and Co., are arranged to drive respectively on to three independent countershafts working in line with couplings ready for connection in event of any one engine being stopped. From this line of countershafting the dynamos are driven by means of belts. The dynamos are supplied by the Brush Electrical Engineering Company, and consist of eight arc light machines each capable of running 35 10-ampere lamps in series, two of which are running idle as spare machines in case of breakdown; two low-pressure direct-current Victoria dynamos used for the large projector arc lamps in the arena section; and one 100-kilowatt Mordey alternator, and one 37-kilowatt Mordey alternator. The larger of the two alternators, working at 2,000 volts pressure, is employed to maintain all the incandescents throughout the building and grounds, numbering 1,000 lamps, also the arc lamp for the luminous fountain, these all being worked in groups from "small transformer sub-stations." The 37-kilowatt alternator supplies the current for the lighthouse only, also transformed down from 2,000 volts. In addition to the above plant a complete set of gas engine, dynamo, and accumulators is in operation to maintain a continuous light for an experiment in plant culture under electric light, daylight being completely excluded. The accumulators here maintain the light during the night.

The 210 arc lamps throughout the building and grounds are of the Brockie-Pell type, supplied by Messrs. Johnson and Phillips. An interesting feature of the outdoor lighting is a small illuminated fountain in the Western Gardens. This has been specially designed by Mr. Fricker, and is a new departure in colour-changing fountains, being perfectly automatic in action and having worked successfully throughout. The light from a powerful arc is thrown horizontally from some 15 yards distance in parallel-coloured beams on to a mirror at 45deg., from which it is reflected vertically through a glass plate under the jet. There are five distinct colours, which succeed each other at an interval of one minute by means of a simple relay and electromagnetic gear. The lighthouse in the central gardens carries one of the most powerful arcs which has ever been used. The current supplied is 250 amperes, and the light is refracted by a set of revolving lenses into 12 separate beams, which, as they slowly sweep the horizon, can be seen for many miles around London. The lighting of Capt. Boyton's Water Show constitutes a large section. There are on the roof around the arena 10 projector lamps, each of about 10,000c.p. to 15,000 c.p., and three search lamps of some 20,000 c.p. to 30,000 c.p. each. In addition to these there are 20 arc lamps of 2,000 c.p., and about 100 incandescent lamps scattered over the ground. The effective result of the whole lighting speaks well for the general scheme, and, at the same time, the fact that there has not been a single failure or hitch of any kind throughout the whole plant in the exhibition bears testimony to the thorough character of the work and the excellence of the machinery. Much must be said for the care and attention which such a successful result necessarily entails, and in this connection Mr. Fricker wishes particularly to acknowledge the valuable co-operation of his foreman Mr. D. F. Adamson, and his assistant Mr. F. Miller, who have had charge of the job. We understand that, as a mark of the appreciation in which Mr. Fricker's services have been held, a special honorary medal has been awarded to him for the electric lighting of the Exhibition.

CORRESPONDENCE.

ON THE USE OR ABUSE OF SECTIONS A & G.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It has sometimes struck me from the tone of letters and Editorials that there may be some dissatisfaction with the mode in which Sectional work at the British Association is usually conducted. For myself I have not felt any such dissatisfaction, because I have thought that for serious publication and recording of new results and other formal purposes societies in London had a preponderating advantage. My idea was that the British Association was best adapted to a conversational account of what was going on, to a friendly and mutually helpful impromptu discussion among the workers, and that serious set Papers to be circulated beforehand and elaborately discussed were out of place. New results are indeed often brought before a Section, but they are usually brought in an informal and preliminary sort of way, sufficient to awaken interest in, and secure attention to, the record when ultimately published, but not constituting the official record itself. So many societies exist for the formal reading of Papers that it would seem to me a pity for Section A and Section G to merely add two to their number. I am only expressing my individual opinion, which may very

Digitized by Google

well be wrong, and if you thought fit to open your paper to a discussion of the matter, perhaps whatever feeling of dissatisfaction may exist would display itself in a manner instructive to future organising committees.—Yours, &c.,

OLIVER J. LODGE.

CHICAGO CONGRESS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is only due to Mr. Preece that I should point out an error that has slipped into the last sentence of my article on the Chicago Congress, where I allude to a reception given to members of the Congress "by the British Commission." To be completely accurate it should run, "given at the house of the British Commission by the President of the Institution of Electrical Engineers." The house was indeed lent for the occasion by the British Commission, of which body Mr. Preece is also an active member, but the inception, arrangements, and expense of the reception fell upon Mr. Preece alone.—Yours, &c.,

SILVANUS P. THOMPSON.

"NEW LAMPS FOR OLD."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to Prof. Ayrton's article in your last issue on the economy of over-running glow lamps, it may be useful to look at the subject from another point of view.

The pith of the matter seems to be in the fact that by putting a few volts extra through the lamps an over proportionate increase of light is obtained, and though the time factor is diminished yet, on the whole, the sum of the candle-hours is increased.

This is the theory. Can it be made use of in practice? Prof. Ayrton says "Yes," inasmuch as he recommends the use of 97-volt lamps on 100-volt circuits, but the real question seems to me to centre upon the necessity for having the extra brilliancy of the lamps and the willingness to pay for a greater number of new lamps to replace the burnt out ones.

In electric installation work, the usual plan being to pay so much for each lamp installed, it is a pretty sure thing that if the contractor has anything of a free hand there will be no lack of light; in most cases the full effects are too dazzling for comfort. This being so, it does not seem conducive to economy to make things so much more brilliant when it is at the expense of the lamp's life, and this argument also applies to cases where there is just a sufficiency of light. If, however, it is possible that a house has been sparsely supplied with lamps, and its occupants want more light, over-running would be probably cheaper than increasing the fittings.

So, then, it would seem that for most already fitted houses over-running is needless and expensive. It may be, however, that future generations of electrically installed houses will reap the benefit of Prof. Ayrton's experiments. Fewer lamps will be required for the same light, thus saving in fittings as well as in the meter, but, as the concluding paragraph of your current leader seems to imply, the inconvenience of a more frequent extinction of lights and the nuisance of replacement have to be considered.

There are other points to this question of over-running, but perhaps the subject is not of sufficient importance to warrant a further intrusion upon your valuable space.—Yours, &c.,

J. H. C. BROOKING.

October 3, 1893.

ALTERNATE-CURRENT MOTOR TESTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In an Editorial note, page 571, September 29, 1893, referring to the article of our engineer, Herr Emil Kolben, you mention a test made by Col. Turrettini at the Geneva Central Station. The alternate-current motor of 10 H.P., which took a starting current equivalent to 37 H.P., is, however, not of Oerlikon origin, as might be suggested by the Editorial paragraph, but has been made by Brown, Boveri and Co., of Baden. The tests with Oerlikon motors did not take place until a few days ago. There was one 9 H.P. and one 12 H.P. alternate-current motor of not quite the same design. Both took a starting current equivalent to 15 H.P., that is to say, with regard to the out-put of the motors, about 2½ and 3 times less starting current respectively than the motor made by Brown, Boveri and Co.

But for the interest attached to the alternate-current motor question, I would rather not have sent you these lines, which might look as if suggested by competition. I would only state, that a motor of 12 H.P. effective, taking a current from the mains equivalent to 15 H.P., is by no means useless, and justifies further additions to the theoretical and descriptive literature on alternate-current motors.—Yours, &c.,

Zurich, September 30, 1893. EMIL HUBER.

[Neither the observation that some so-called self-starting motors are almost useless on account of the excessive starting current, nor the allusion to the 10 H.P. motor at Geneva, referred to the Oerlikon Company. We had no confirmation of the test from the makers of the motor, and therefore omitted their names.—Ed. *E.*]

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

"DRUM ARMATURES AND COMMUTATORS."—This book, which is written by Mr. F. Marten Weymouth, and is the latest addition to *The Electrician* Series, is now ready, and will be sent direct by the publisher on receipt of the published price, 7s. 6d., or it may be obtained from any bookseller. A prospectus will be forwarded on application.

TENDERS INVITED.—The Northern Co-operative Company invite tenders for the supply of an electric lighting plant for their central premises at Aberdeen. Specifications may be obtained from the Secretary, Mr. John Ferries, to whom tenders must be sent by the 25th inst. Further particulars appear in our advertisement columns.

——— Mr. N. J. Psiachi, of Cairo, invites tenders for the electric lighting of some buildings in that city, with about 1,500 glow lamps of 10 c.p., and 12 arc lamps of 350 c.p.

——— The Electric Lighting Committee of the Lancaster Corporation invite tenders for the brickwork, &c., required in the fixing of two boilers, and a set of economisers at their electricity works. Tenders are to be in by Wednesday next, the 11th inst.

——— The St. Pancras Vestry are prepared to receive tenders for the building of the chimney shaft at the East St. Pancras Central Station, King's-road, N.W. Tenders are to be in by October 16th.

TENDERS RECEIVED.—The Technical Instruction and Public Library Committee of the York City Council recommend the lighting of the Institute building by electricity, and also suggest that the tender of Messrs. Benson and Co., of London, for wiring the building for the sum of £314 be accepted.

TENDERS ACCEPTED.—The Gas Committee of the Aberdeen Town Council have accepted the tender of Messrs. Crompton and Co. (Limited) for the supply of copper connectors for the electric lighting plant.

APPOINTMENTS VACANT.—The School Board for London want, for the training-ship "Shaftesbury," an electrical engineer and a stoker mechanic, to take charge of the electric lighting apparatus. Applications to be sent to the Clerk of the Managers, School Board Offices, Victoria Embankment, W.C., by the 13th inst. Particulars will be found in our advertisement columns.

FOR SALE.—Messrs. T. F. Ashe and Nephew, of Atherton-street, Liverpool, announce in our advertisement columns that they have for sale 30 E.P.S. L type accumulators with accessories complete; also slate switchboard, &c., for use with same.

PERSONAL.—Mr. Lee has been appointed engineer to the Southampton Electric Light and Power Company (Limited), in place of Mr. K. A. Scott Moncrieff, who has left to join Messrs. Kilburn and Co., the Calcutta agents for Crompton and Co. (Limited).——Mr. C. J. Robertson has severed his partnership with, and his duties as Technical Director to, the "Watt" Glow-lamp Factory of Vienna, and has now joined the Incandescent Electric Lamp Company (Limited), of Brook-Green Works, Hammersmith, W., as their engineer and managing director.

REMOVAL.—The Secretary of the Crocker-Wheeler Electric Company announces that "Ampere is now their ohm," which, being interpreted, is that the town of Ampere (N.J.) is now their home and abiding-place. This is current news.

Digitized by Google

MR. N. F. NALDER.—This gentleman informs us that he has commenced business at 8 and 10, Charing Cross-road, W.C., as a manufacturer and repairer of all kinds of electrical instruments, &c.

BANKRUPTCY.—A receiving order has been made against William Andrews, lately trading at 118, Hunger Hill-road, Nottingham, as an electrician.

ELECTRICAL TRADES UNION.—A new branch of this Union is to be opened on Monday, October 16th, at the "Swan" Tavern, Caledonian-road, N., at 8 p.m.

THE SILVERTOWN CABLE COMPANY.—We have recently received copies of the revised catalogues and price lists of the cables and other electrical goods manufactured by the India-Rubber, Gutta Percha, and Telegraph Works Company, at Silvertown. From a comparison of these with the previous issue we find that the classification of cables is not appreciably altered; but we are glad to notice that the prices of almost all the classes of cable goods rule substantially lower than before. The excellent character of the Silvertown cables is well known in the trade, and is above criticism. This firm also supplies dynamos, batteries, and electrical fittings.

STEAM-SAVING APPLIANCES.—The steam-saving appliances, described in a pamphlet we have received from Messrs. McDougall and Co., comprise a steam trap, which ejects automatically, and without loss of steam, a steam separator or dryer, which returns the water in the steam to the boiler, anti-priming apparatus, mechanical stokers, and sight-feed lubricators. It will be seen that Messrs. McDougall and Co. have attacked the important problem of steam and fuel economy at almost every possible point.

INCANDESCENT LAMPS.—With reference to the Trade Note in our last week's issue respecting the purchase of the Brook Green Works, Hammersmith, we learn that these works have been started by the Incandescent Electric Lamp Company (Limited) to manufacture Mr. C. Robertson's incandescent lamp. The General Electric Company (Limited) are largely interested in the new Company, and have undertaken the sale of the lamps.

MESSRS. DRAKE AND GORHAM.—This firm have obtained the contract for the lighting of Messrs. Agnew and Sons' picture gallery at Manchester, where about 160 lights will be installed. Messrs. Drake and Gorham's Manchester staff are, we understand, also busy on several other installations in the district.

ELECTRIC PUMPING PLANTS.—Messrs. Ernest Scott and Mountain (Limited), of Newcastle-on-Tyne, have contracted with the Lothian Coal Company, Newbattle Collieries, Dalkeith, for the supply of two electric pumping plants. The plant will consist of two compound horizontal condensing engines, each engine to be capable of giving 120 effective horse-power, which will drive two "Tyne" dynamos, each capable of giving an output of 60,000 watts. The pumps are placed at the bottom of the pit, each set being capable of delivering 200 gallons of water per minute against a head of 600ft.; they are driven by "Tyne" electric motors.

BEDFORD.—In June last the Town Council met to consider the tenders which had been received in reply to an advertisement respecting the carrying out of the powers granted under the Corporation's Provisional Order. Mr. F. H. Medhurst, of Cambridge, made two alternative propositions—one that the Provisional Order be transferred to himself, and in the other he offered to supply a complete installation for the sum of £24,000; Messrs. C. A. Parsons and Co. offered to lay down plant at a cost of £12,000, exclusive of buildings; and a third offer was from the Bedford Electric Light Company (Limited). The Town Council were recommended by the Electrical Sub-Committee to accept the latter. The matter was, however, remitted to the Sub-Committee for further consideration, and their report was presented to a special meeting of the Town Council held on Thursday last week. A long and somewhat acrimonious discussion ensued, with the result that a resolution to hand over the Corporation's powers to the Company was carried by a small majority.

BLACKPOOL.—The Town Council, it will be seen by an advertisement in another column, have decided to hold a grand electrical *fête* on the occasion of the inauguration of the Corporation electricity works on the 18th inst., when the new arc lamps along the promenade will be lit for the first time; and it is proposed also to festoon the whole length with incandescent lamps. The tower will be outlined from top to bottom with incandescent lamps, surmounted by a group of arc lamps and a powerful search-light. There is also to be a grand illuminated cyclists' parade. Lord Kelvin is to speak at the subsequent banquet.

CHICHESTER.—The Lighting Committee of the Town Council reported at the last meeting of that body that they had appointed a sub-committee to interview the Gas Company's representative, and that they had under consideration the question of introducing the electric light, but they had not yet arrived at any decision.

CHELSEA.—The Chelsea Board of Guardians have decided, in reply to a letter from the Chelsea Electric Supply Company, not to take any action in the matter of electric lighting at present.——Upon a letter being read from the London Electric Supply Corporation at the meeting of the Vestry on Tuesday, as to their supplying the Vestry Hall with electric light, it was resolved to refer the matter to the Hall and Electric Lighting Committees in order that the question could be thoroughly gone into.

DEWSBURY.—The Electric Lighting Committee of the Board of Guardians, with reference to the tenders for lighting the workhouse, &c., recommended the Board to formulate a specification based upon the several tenders received, which should also be made to provide for the lighting of the cottage homes, and to contain a clause to guarantee the proper and effective lighting of the workhouse, &c., for a reasonable period thereafter, and that the tenderers submit tenders in accordance with such specification. The Chairman of the Committee said they had gone very carefully into the matter, and they had come to the conclusion that the cost of lighting the premises by electricity would be less than by gas. After a short discussion, the Board adopted the recommendation of the Committee, and likewise decided to apply for power to borrow £2,100 for electric lighting purposes.

DOVER.—The Brush Electrical Engineering Company have laid before the Electric Lighting Committee of the Corporation the proposed Memorandum and Articles of Association and prospectus of the Dover Electric Supply Company (Limited), and the committee have recommended the Council to approve of the same. We understand that the Tennis Club Ground in Park-street has been selected as a site for the central station in the event of the Company being successfully floated.

DUNOON.—The Police Commission have agreed to a recommendation of their Lighting Committee that they refuse consent to the Caledonian Electric Supply Company's proposal to apply for a Provisional Order, and that the question of introducing the electric light into the burgh be remitted to the committee for consideration.

GREAT MISSENDEN.—A meeting was recently held in the schoolroom to further consider whether the Lighting Act should be adopted in the district comprising the village only, and also to consider a proposition of the British Volt Electric Glow Lamp Company to provide all the plant and fittings at their own cost, and also to provide 13 electric lights each night from September to March, for all hours from one hour after sunset to 10:15 p m., on condition that the charge to the village shall not exceed £15 per year. There was a large attendance, and it was resolved to accept the proposition of the Company.

GRIMSBY.—The Public Lighting Committee of the Corporation had the question of electric light again under consideration at their meeting on Monday, when the surveyor said that he had not yet received replies from all the local authorities with whom he had communicated as to the cost, &c. It was decided to appoint a sub-committee with a view to obtaining a Provisional Order.

LAMBETH.—The Board of Guardians at their meeting on Wednesday week took into further consideration the report of Mr. W. H. Preece upon the electric lighting of the workhouse and infirmary, and finally resolved to take no further steps regarding the scheme.

LEAMINGTON.—It has been decided to light the parish church by electricity at an estimated cost of £250.

LONDON COUNTY COUNCIL.—At the meeting on Tuesday the Finance Committee reported the result of the negotiations with the Treasury on the subject of electric lighting loans, consent having been given to the inclusion in such loans, spread over not more than 50 years, of the whole initial cost of the undertakings. This was subject to the general understanding that the Council would be professionally advised on each case, and that where any considerable proportion of the amount of a loan was for "short-lived purposes" the fact would be considered in fixing the period of the loan. On the recommendation of the same committee a loan was granted to the Vestry of St. Pancras of £8,000 for electric lighting purposes. It was also agreed: "That it be referred to the Highways Committee to consider how far the proposed agreement about to be made between the National Telephone Company and the postal authorities will affect the Council's position in regard to the telephone service in London, with power to confer with the Postmaster-General."

LYNTON.—The Local Board have had an offer from Mr. Benn to sell the electric light works to the Board. The Board were already paying £143 for lighting, and if they would add another £50 to that amount he said he would hand over the works and undertake it. He estimated that the working expenses amounted to about £250, and the revenue from private consumers came to £400. After the lapse of 42 years the undertaking would become the absolute property of the Board. A special meeting of the Board was to be held to consider the offer.

NORWICH.—The Secretary of the Norwich Electricity Company (Limited) notifies the public that the consumers of electricity who have been supplied with current up to October 1st by Messrs.

Digitized by Google

Laurence, Scott and Co. (Limited) will in future be supplied by his Company.

PETERBOROUGH.—The Town Council on Thursday last week decided to apply to the Board of Trade for a Provisional Order enabling them to supply electricity within the borough. An abstract of the Borough Engineer's report on the subject appeared in last week's *Electrician*.

PORTISHEAD.—In reply to advertisement requesting tenders to be sent in for lighting the public lamps, the Local Board received three tenders, one for an installation of an electric lighting plant, and the others for lighting the district by oil and by gas. The electric lighting tender suggested the purchase of plant to the amount of £12,450, the tender for lighting by oil worked out at £2. 4s. 6d. per lamp, while the local gas company offered to light the lamps at £2. 2s. each. After a short discussion, the tender of the gas company was accepted.

SHEFFIELD.—The Sheffield Electric Light and Power Company obtained Parliamentary powers in June, 1892, for the electric lighting of the city, and they will soon be in a position to generate electricity sufficient for the supply of 150,000 lamps. Applications for current have been numerous enough of late to confirm the Company in their opinion that their action will be appreciated. The main station is in process of construction at the bottom of Commercial-street, and eight converting stations or transforming chambers have been erected in various parts of the city, the power for the whole of which is to be derived from the central station. Current will be supplied from the central station at a pressure of 2,000 volts to the various transforming stations. The high-pressure system has been adopted in Sheffield on account of the large area to be dealt with—an area which includes every part of the city. As soon as the underground work in connection with the compulsory area is complete the Company will proceed to extend the wire to the Broomhill and Ranmoor districts, where a large demand for the current is anticipated. The work connected with the reconstruction of the central station is being vigorously proceeded with. Five Babcock and Wilcox boilers have already been put down, and two additional engines and alternators, manufactured by the Brush Electrical Engineering Company, are being erected. There are a number of Mordey-Victoria alternators working at a pressure of 2,000 volts: these are rope-driven from high-speed vertical engines. The supply of electricity to consumers is made at present from overhead wires, but the wires which will supply the city under the new scheme will pass underground. The construction of the last transformer chamber is now complete, and nearly all the underground work is finished. The mains have been laid on the Callender system.

SUNDERLAND.—The Highways Committee of the Sunderland Corporation had under consideration at their last meeting the report of Prof. Kennedy on the scheme of electric lighting for some of the principal streets. The committee decided to obtain further copies of the ten sets of plans, and to have complete specifications made out in accordance with Prof. Kennedy's suggestions, and also to advertise for tenders from electrical engineers for supplying and fixing the plant. It is proposed to utilise Dunning-street Hospital as a central station.

TAUNTON.—A special meeting of the Town Council was held on Monday, when the borough seal was affixed to the contract with the Taunton Electric Lighting Company (Limited) for the purchase of their works and plant. It was stated that Dr. Fleming had been interviewed as to the carrying on of the work, and he would report in due course.

WEST HAM.—The Town Council have decided to defer for six months the question of the electric lighting of the borough.

WOKING.—We understand that the great demand for the electric light at Woking has necessitated extensive additions to the plant of the Woking Electric Supply Company, extra machinery having been added, which will enable the Company to double their production.

PATENT RECORD.

A record of Applications for Patents and Patent Specifications Published is compiled for this journal by MR. J. C. CHAPMAN, *Fel. Chartered Inst. Patent Agents, of 70, Chancery-lane, W.C., from whom any information on the subject may be obtained.*

APPLICATIONS FOR PATENTS.

September 15, 1893.

17,341. G. KAPP. Manchester. Improvements in alternate-current dynamos.

17,348. H. W. BOWDEN and W. BOBY. London. Improvements in electrical transformer street surface boxes.

17,352. T. W. SCHMIDT. Bradford. Improvements in electrically controlled arc lamps.

17,372. H. LÜDEKE, E. L. A. LÜDEKE, A. J. THORMAN, E. DE BUNSEN, and E. M. HORE. London. Improvements in magneto-electric motors.

September 16, 1893.

17,445. W. H. SCOTT. Norwich. Improvements in pipe conduits for electric mains.

17,447. W. M. HUSKISSON. London. An automatic submarine mine and sentinel.

17,466. W. WRIGHT and J. B. HAMOND. London. Improvements in the treatment of zinc produced by electrolysis.

17,493. J. B. C. DION. London. Improvements relating to thermo-electric batteries and to apparatus for use in the manufacture of the same.

September, 18 1893.

17,501. W. FIELDER. London. Improvements in, and connected with, alarum clocks, and electrical signalling appliances.

17,521. J. JACKSON and W. DIXON. Glasgow. An important method of illuminating by the electric arc.

17,526. R. J. CROWLEY and W. C. COX. Queenstown. Improvements in, or relating to, fac-simile telegraphy.

17,557. E. COMMELIN. Liverpool. Improvements in electric meters.

17,564. A. KOCH. London. Improvements in electric accumulators.

September 19, 1893.

17,603. A. S. ATWATER. London. Arc lamp.

17,605. W. S. FREEMAN. Otford. Improvements in dynamos and dynamo motors.

17,618. C. ERBEN and E. BERGMANN. Liverpool. Improvements in electric meters.

17,631. H. NEWMARCH. London. Improvements in, and connected with, alarm clocks and electric sound signalling appliances.

17,645. H. H. GRENFELL and O. MARCH. London. Improvements relating to the distribution and regulation of electric current.

17,646. T. W. NESS. London. Improvements in telephone switch operating mechanism.*

17,658. R. W. BARKER. London. Improvements in current conveyors for electric railways. (The Lawrence Electric Company, United States.)*

September 20, 1893.

17,666. W. I. G. LEWIS and E. J. BRADLEY. Newcastle-on-Tyne. Lithophonique porcelain shades for the electric light.

17,690. R. J. CROWLEY. Queenstown. Improvements in or relating to the transmission of electricity and sound along a conductor without a return circuit, and a means of reducing electrical resistance in the air, earth, or sea.

17,692. E. COUSTAU. London. An electric match.

17,729. A. KELVIE. London. An improved convertible combination lamp for electric light, gas, oil, or candle fittings for general advertising.

September 21, 1893.

17,735. J. A. MCNAUGHTON. Manchester. Improvements in the construction of electric appliances applicable to corsets.

September 22, 1893.

17,796. R. KENNEDY. London. Improvements in electric arc lamp regulators.

17,804. F. L. BERNERS and J. L. HIGGS. London. Improvements in, or connected with, secondary batteries.

17,830. G. ABBOTT. Tunbridge Wells. A new and improved galvanic battery, to be called a cartridge shell battery. (J. J. Pearson, United States.)

17,860. E. J. CLUBBE and A. W. SOUTHEY. London. Improvements in electrically propelled vehicles.

17,866. L. W. SCHÖFFER and G. E. W. SCHÖFFER. London. Improvements in apparatus for the electrolytical decomposition of brine and other liquids.

September 23, 1893.

17,874. H. WALKER. Birmingham. Improvements in globe-holders for gas, oil, or electrical purposes.

17,933. J. HOPWOOD. London. Automatic supply fuse for electric supply currents, and in apparatus connected therewith.

September 25, 1893.

17,972. A. MILLS. London. Improvements in make-and-break contacts for electric bells, fire and burglar alarms, and other purposes.

17,980. P. B. W. KERSHAW. London. Improved process and means used therein for the electrolytical production of gases.

17,981. J. DRACH. London. A magneto-electrical igniting apparatus.

Digitized by Google

17,992. C. JOST. London. An improved composition, and the production therefrom of blocks, slabs, tubes, vessels, or like articles, more especially intended for the production of paving blocks or slabs, or conduits for electric cables.

September 26, 1893.

18,019. J. H. TUCKER. Birmingham. Improvements in electrical switches.

18,038. Sir C. S. FORBES, Bart. London. Improvements in microphones.

18,061. THE EDISON AND SWAN UNITED ELECTRIC LIGHT COMPANY (LIMITED) and P. H. BELL. London. Improvements in electric switches.*

18,066. W. R. LAKE. London. Improvements in and appertaining to adjustable supporters for electric lamps and other objects or articles. (O. C. White, United States.)*

18,067. W. H. SHARPLESS. London. An improved form of electric switch.

September 27, 1893.

18,115. F. J. BORLAND. London. A new or improved electric arc lamp, specially applicable for projecting purposes instead of the lime-light.

18,117. H. INGRAM and A. INGRAM. Liverpool. Improvements in brush holders for dynamo-electric machines and electric motors.

18,150. V. C. DOUBLEDAY. London. A portable secondary battery lamp for use in mines and other places. (M. Sussmann, Germany.)

18,165. A. A. GOLDSTON. London. Improvements in and connected with electric switches for series circuits.

18,170. J. S. RAWORTH. London. Improvements in electrical contacts.*

18,173. J. HARGREAVES and T. BIRD. London. Improvements in apparatus for the electrolysis of chlorides and other salts.

18,175. O. FRANZ and G. OTTO. London. Improvements in switchboards for telephone exchanges.*

September 28, 1893.

18,187. T. SLOPER. Devizes. Improvements in or relating to electric telephones.

September 29, 1893.

18,291. H. A. TAYLOR and J. A. L. DEARLOVE. London. Improvements in or appertaining to submarine telegraph and like cables.

18,323. H. H. LEIGH. London. Improvements in electric batteries. (A. Chevalier, France.)

23,101A, '92. C. A. J. H. SCHROEDER and H. E. R. SCHROEDER. London. Improved methods of recovering zinc from the waste products of galvanic batteries.

(Date claimed under Patents, Rule 19, December 15, 1892.)

23,101B, '92. C. A. J. H. SCHROEDER and H. E. R. SCHROEDER. London. New or improved galvanic batteries.

(Date claimed under Patents, Rule 19, December 15, 1892.)

September 30, 1893.

18,346. E. W. P. COMMENS. Birmingham. Improvements in electric switches.

18,363. S. O. COWPER-COLES and SIR B. W. WALKER, Bart. London. Improvements in electro-plating.

18,375. J. A. MONTEALEGRE. London. Improvements in or relating to the arrangement of electrical circuits and switches.

NEW COMPANIES, STATUTORY RETURNS, &c.

OMNIBUS AND TRAMCAR ELECTRIC LIGHTING COMPANY (LIMITED). This Company was registered on September 28th with a capital of £60,000, in £5 shares, to acquire all or any part of the shares, works, undertakings, business, property and liabilities of the Universal Electric Lighting Company, to generate, produce, store, accumulate, and distribute electricity, electromotive force, or other similar agency for the purpose of lighting omnibuses, tramcars, cabs, and other vehicles, public or private buildings, manufactories, mines, ships, lighthouses, railways, and other places and things, to carry on the business of electricians, electrical engineers, mechanical engineers, and manufacturers of electrical appliances, &c. The subscribers (with one share each) are:—A. W. Stormont, 6, Cambrian-road, Richmond; A. L. B. Kerr, 5, Queen's Club-terrace, Kensington; W. J. Griffiths, 43, Finsbury-square, E.C.; J. F. Rogers, 108, Penton-place, Kennington, S.E.; J. A. Lloyd, 54, Florence-road, N.; H. H. Clayson, 27, Borthwick-road, Stratford, E.; and R. Wolfenden, 11, Great George-street, S.W.

HEAD, WRIGHTSON AND COMPANY (LIMITED).—The annual return of this Company, made up to July 1st, has been filed. The whole nominal capital of £210,000, in shares of £5, had been taken up, subscribed for, and fully paid, 98 share warrants of 20 shares each, 140 of 10 shares each, 200 of 5 shares each, and 494 of 1 share each, are outstanding, the value being £24,270. Share warrants representing 25 shares have been surrendered during the last financial year.

MADRAS ELECTRIC TRAMWAYS COMPANY (LIMITED).—This Company has recently entered into an agreement with the Electric Construction Company (Limited) for the supply of plant and materials for use in the construction of their tramway at Madras under a concession granted by the Municipality of Madras, with the approval of the Government. The price to be paid is £58,950, of which £19,650 will be satisfied by the allotment as fully paid of 19,650 shares of £1 each, Nos. 14,928 to 34,577 inclusive.

CITY NOTES, &c.

BRAZILIAN AND SUBMARINE TELEGRAPH COMPANY (LIMITED).—The accounts of this Company, subject to audit, show a profit sufficient to enable the Directors to recommend a final dividend of 3s. per share, making, with previous distributions, a total dividend of 6 per cent. for the year ended June 30, 1893, and also the payment of a bonus of 1s. per share, both free of income-tax, which together will amount to £26,000, leaving a balance of £10,533, of which amount £7,000 has been placed to the reserve fund, increasing that fund to £638,675, and £3,533 carried forward. For the purpose of paying the above dividend and bonus on the 19th inst., the Register of Transfers will be closed from the 10th to the 18th inst., both days inclusive.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended October 1st were £795, as against £786 for the corresponding period of last year, being an increase of £9. The total receipts for the half-year amount to £10,449, against £9,994 in the corresponding period of 1892, being an increase of £455.

CUBA SUBMARINE TELEGRAPH COMPANY (LIMITED).—The estimated traffic receipts for the month of September are £3,000, as compared with £3,295 in the corresponding month of last year.

DIRECT SPANISH TELEGRAPH COMPANY (LIMITED).—The gross receipts for the month of September were £1,865, as compared with £2,011 for the corresponding period of last year.

EASTERN TELEGRAPH COMPANY (LIMITED).—The Company announce the payment by warrants, on November 1st, of interest for the half-year ending October 31st, on their Four per Cent. Mortgage Debenture Stock. The transfer books will be closed from October 27th to November 1st, both days inclusive.——The traffic receipts for the month of September, 1893, amounted to £55,997, and to £55,710 in the corresponding period of 1892.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the month of September, 1893, amounted to £39,339, and to £42,585 in the corresponding period of 1892.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY (LIMITED).—This Company notify that on Tuesday, November 14, 1893, at noon, at the Company's offices, Winchester House, Old Broad-street, E.C., 345 Five per Cent. Mortgage Debentures will be drawn for payment on January 1, 1894. Notice will be given by advertisement of the numbers of the debentures drawn.——The Company also announce the payment by warrants, on November 1, 1893, of interest on their Four per Cent. Mauritius Subsidy Debentures in respect of instalments paid to October 31, 1893. The transfer books will be closed from October 27th to November 1st, both days inclusive.

LIVERPOOL OVERHEAD RAILWAY COMPANY.—The Directors last week issued a prospectus, inviting subscriptions for £25,000, in 2,500 Five per Cent. Perpetual Preference shares of £10 each, making, with £75,000 already issued, £100,000 out of a total authorised Preferential capital of £120,000. 10s. per share is payable on application, 30s. per share on allotment, and the remainder in calls not exceeding £2 a share at intervals of not less than three months. The list of applications opened on Tuesday and closed yesterday (Thursday).

W. T. HENLEY'S TELEGRAPH WORKS COMPANY (LIMITED).—Dividend warrants have been posted for the half-yearly interim dividend on the Preference shares at the rate of 7 per cent. per annum.

Digitized by Google

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended September 29, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,314.

WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED).—The receipts of this Company for the two weeks ended September 30th were £1,765, as compared with £2,491 for the corresponding period of last year.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 804.—Vol. XXXI. FRIDAY, OCTOBER 13, 1893. PRICE FOURPENCE. *Annual Subscription (U.K.), 19/6*

NOTES.

Prof. Ayrton's letter, which will be found in our correspondence columns, coming as it does from one who not only has lately returned from Chicago, but who has given considerable attention to the testing of glow lamps, assures us that the tests which are being carried out in connection with the Chicago Exhibition are being conducted with great care and under able supervision. This we are glad to learn. We cannot, however, admit that we have condemned the labours of Prof. Thomas and his assistants; they will, doubtless, yield many interesting scientific results. Our criticism related to the prospect of the information obtained being of commercial and practical use. Prof. Ayrton asks why we object to the maintenance of a perfectly steady pressure. We reply that, for a scientific test, such a pressure is desirable, but that it does not correspond with the conditions of practice. Some day house-agents will advertise "a desirable mansion situated near a feeding point," and in such a house the pressure should be fairly steady. But even recording voltmeters show very considerable variations of pressure in most parts of London, and the minor variations which such instruments are unable to register, chiefly on account of the inertia of their moving parts, probably have a marked effect on the life of lamps. We do not see how it is possible to specify a variation of pressure. The Board of Trade impose limits, but the nature of the variation, and, what is most important, the duration of the periods of high pressure, affect the life of lamps, not the mere limits.

We are not at all sure whether, as Prof. Ayrton suggests, the removal of lamps to the photometer bench will cool them "as in practice." A fairly long test seems to be necessary, because it is only by the behaviour of long-lived lamps that we can judge of the economy of forcing them. The short lives which Prof. Ayrton advocates depend on the falling-off of candle-power, and this falling-off is undoubtedly greater when the lamp is forced. If there are any lamps which maintain their candle-power even at a slightly increased consumption of energy, their long and steady lives may offer some advantages. But 360 different lamps, limited to 40 of each voltage, or 80 of each make, are not, we think, sufficient. Do not the different batches of lamps turned out, even by makers so careful as the Edison and Swan United Company, differ very considerably? and we should imagine that with the unsettled state of the lamp industry in America, variations between batches would be almost as great as differences between different "makes."

A table intended to show the comparative cost of gas and electric light will be found in another column. It is said to emphasise the information in as lucid a manner as it can be stated. It was addressed to an Association of Gas Managers, who are, no doubt, very clever men, and took it in at a glance, but we must confess that we spent some time in calculations and cross-checking before we understood it. There is an attractive symmetry about it, and the explanation, which we believe to be necessary, will be found in a footnote to it. We are fully cognisant of the rosy optimism of many electrical authorities who declare that electric light is already as cheap as gas, but we have always been opposed to these sanguine calculations. A fairly good rule was, to multiply the number of pence per unit by ten, to get the equivalent price of gas. For example, electric supply at 6d. is equivalent to gas at 60d. or 5s. per thousand cubic feet. This assumes about 4·17 watts per candle for the glow lamp and 2·4 candles per cubic foot for the gas burner. Thus, an 8-c.p. lamp taking 33·3 watts consumes one unit in about 30 hours, giving 240 candle hours for 6d. Sixpennyworth of gas, on the other hand, at 5s. per thousand is 100 cubic feet, and this at 2·4 candles per cubic foot gives the same amount of light.

The table by Mr. Terrace assumes gas at 2s. per thousand, and the costs of 3,333 candle-hours with five different kinds of burners are given. The burners "as commonly used" are put at only 1½ to 2 candles per cubic foot. The obscure columns on the left-hand side of the table give the "number of units said to be equivalent to 1,000 cubic feet of 16 candle gas," and the cost at 6d. per unit. Ten units are said to be "allowed by the Board of Trade." What the Board of Trade has got to do with glow lamps we fail to comprehend. We are tolerably familiar with the doings of the Electrical Department of the Board of Trade; we doubt even that Mr. Terrace has any private information from the Department, but no number of units is "allowed" or "said to be" allowed by the Board. Reducing this mysterious allowance to figures, we find that it implies running a lamp at 3·33 watts per candle. Until the price of lamps was reduced this would have been generally considered a little too high pressure, but

Digitized by Google

Prof. AYRTON now recommends about 3 watts per candle. "Practical men," gas managers, we presume, are said to "estimate" 12½ units to be equivalent to 1,000 cubic feet of gas. This means, according to the suppressed assumption on which the table is based, 3·75 watts per candle. This is better, but we took more than 4 watts. "One-sided advocates say," according to this high gas authority, 6 units. Possibly our idea that the 3s. means the cost of 3,333 candle hours is wrong, but, assuming that it is right, since the table is otherwise incomprehensible, 6,000 watt hours yield 3,333 candle hours; therefore the lamp must give 1·8 watts per candle. This is perfectly absurd. We greatly regret the over-confident and careless comparisons which have been made by electrical engineers, and which have very properly been criticised by the gas journals; but we challenge Mr. TERRACE to give the names of his one-sided advocates who recommend 1·8 watts per candle; or invite him to explain his table.

IN volunteering advice to young couples who are called upon to decide whether or no they will have the electric light, the *Pall Mall Gazette* admits that the light is much cleaner than gas, but observes that "the rent of the meter will be at least £1 a year," and that "the popular idea of lamps lasting a thousand hours is altogether a myth. Some may possibly do so, but many do not, and some last but a few weeks." Speaking of hours and weeks in the same breath is rather ambiguous. Six weeks contain about a thousand hours; but reckoning an average of two hours a day, six weeks represents only eighty hours of lighting. This is hardly fair to the manufacturing monopolists, who, with all their severity towards small contractors, have been generally ready enough to exchange lamps that have, through no fault of the consumer, broken down after an unduly short life. "Meanwhile, seeing that each light costs about four shillings, to replace them frequently is an expensive matter, and adds much to the cost of the light." This might pass for one of the usual careless misstatements of daily papers when they deal with matters even indirectly connected with science. But immediately facing this is a note, abstracted without acknowledgment, by the way, from the second page of our last issue. The only excuse for the error (the borrowing of a note is a trifle) is that the one is in a column of gossip and the other in "Science Notes."

THE adoption of a frequency of only forty alternations per second for the Derby electric supply is a step which, however defensible it may be on certain grounds, cannot be said to follow the lines of general English practice. The whole question involves, of course, the choice between convenience in alternate-current motive power distribution in its present imperfect state of development, and the plant efficiency of the generating and transforming machinery. The system is one of simple single-phase, and the introduction of a frequency of less than half the common figure will no doubt simplify matters where alternate-current motors have to be adopted. But, at the same time, it cannot have escaped the engineers who have designed this station, that there is rather a high price to pay for practice of this sort. Far-sightedness is an excellent quality in central station designers, and it is always well to provide for the demands of a few years' time. But it is possible to see too far; to cast one's eyes so far into the future as to forget the immediate claims of the present. Motive power will have to be provided by central stations in abundance, in a few years time, there is no doubt; but is it likely that the demand for the present and immediate future will justify such a departure from ordinary practice? Considering the possibility of a motor being in the meantime invented that will work with ordinary frequencies, would it not have been better to pay more attention to the lamps and to the plant efficiency of the machinery?

THERE is one element of danger in the penny-in-the-slot meter as applied to gas consumption which has been rather overlooked, and which is absent on electric lighting circuits, namely, the risk of gas escapes and explosion which arises from automatically cutting off the gas supply without closing the separate gas taps at the burners. When the gas is cut off at the meter, and afterwards turned on again by the dropping of the necessary penny into the slot, a forgotten gas jet may lead to very serious consequences, unless, indeed, each individual gas burner is to be provided with an automatic valve.

AN enterprising American has started a school of applied electricity which will be "conducted entirely on the correspondence method." This is surely the nemesis of the cramming-up-for-examination system; "students" stuffed with paper, fed on science, falsely so called, without ever seeing, far less handling, apparatus! When we have reached a stage at which swimming can be taught to perfection on a blackboard, and when the sight of the chemical formula for bread will satisfy the pangs of hunger, but not till then, will the paper age or *astræa redux* of technical education succeed in fulfilling any useful purpose.

INVENTORS not infrequently reveal a depth of unconscious humour in the products of their ingenuity, but rarely do we come across such an invention as that which has recently made its appearance in France in the shape of an automatic apparatus for preventing a consumer placing more than the proper load on his lighting circuit. In Brighton Mr. WRIGHT places a maximum recording instrument on the mains, and by a very simple system, which we described not long ago, a great concession is made to consumers, while the load is equalised and considerably increased. In Leeds it was proposed to allow the consumer to do what he pleased up to the very uncertain limit fixed by the main fuses. But the French inventor has decided otherwise, and elects to place in the circuit an electromagnetic device which will absolutely prevent more than the proper number of lamps being run at any one time. This would be bad enough if the device cut out the lights and left the would-be customer in darkness, as was threatened at Leeds; but the humour of the inventor leads him to perpetrate a more truly awful invention. When the extra lamp is put into the circuit in which it has no lawful

Digitized by Google

place, an ingenious arrangement of springs and electromagnets causes the current to be alternately switched on and off again in rapid succession, thus making an irritating flicker in the lamps on the whole circuit controlled by the regulator. Imagine the state of affairs in, say, a crowded hotel, brought about by someone accidentally or purposely placing an extra lamp on the circuit, or by a bad fault in the wiring. How long the "alternate extinction and relighting" of the lamps would continue we cannot say; except that it would be until the machinery in the regulator had run down. When that stage was reached a metal bob in the exhausted regulator would drop forward and put an end to the agony by total and uninterrupted darkness. But this stage would not have been reached till 2,700 fluctuations of the light had been inflicted on the distracted and unhappy consumer. The idea must have originated in the well-known phenomenon attending the presence of water in a gas pipe.

Mr. A. A. Voysey has announced in a contemporary a "new danger." It consists of a combination of a table-cloth of fluffy material interspersed with fine metallic threads, and a neighbouring thunderstorm. The metal threads are "acted upon inductively by the lightning discharges," and the fluffy material is set on fire. Mr. Voysey advises persons who have such table-cloths, and other "combinations" that are "capable of becoming dangerous during a storm," to "take a quiet walk round his premises during or after any very severe thunderstorm." To destroy such table-cloths would be a feeble expedient. Fashion in her irresistible progress may dictate the use of such fabrics, but does not science also march onward? In these days of grandmotherly interference by county councils, municipal authorities, and Parliament, with our private concerns, should not "something be done"? A complete metallic cage might be built round the house, but this is clumsy. A better way would be to pass a short Act empowering the Board of Trade to make regulations for securing the safety of the public. A schedule of fluffy materials would be given, and a minimum impedance in milli-henrys per square metre of metallic ornament would be ordered. At last there would be some use for the secohm-meter—no household—or, at all events, no draper's shop—should be without one. Mr. Trowbridge's observations, which are recorded in another column, suggest that the triple combination of electric wires, leaky gas-pipes, and a thunderstorm is fraught with danger, but here even the sechom-meter or a lightning protector seems useless. The remedy, however, is simple—remove the gas-pipes.

California Midwinter International Exposition.—We have received particulars of an exhibition which it is intended to hold at San Francisco next December. The exhibits are to be of a general and international character.

Erratum.—Throughout the article on "Iron for Transformers" which we published on page 623, last week, the expression $S\,H\,d\,I$ should read $\int H \,.\, d\,I$, this expression giving the cyclic integration of the magnetising force with respect to the intensity of magnetisation.

Bristol.—A Bristol newspaper complains of the heavy character of the arc-lamp poles, which, it says, are quite unsuited to the narrowness of the streets. But it consoles itself with the reflection that there is some excuse for these massive castings "if they are taken as a symbolical assurance that there is no fear of a breakdown" of the electric lighting plant.

Electric Light in H.M. Navy.—Opportunity is being taken in Chatham Dockyard to have the electric lighting arrangements of the whole of the first-class armoured battleships fitting and preparing for sea improved. The electric lighting of the ships is being taken in hand by private electrical engineering firms, the battleship "Howe" being already completed. New electric lighting apparatus will also be fitted to the battleships "Monarch" and "Agincourt."

A Street Conflagration.—Occasionally, but very rarely, it will happen that circumstances combine to produce disaster as they have recently done on the electric tramway of Budapest. A large carboy of benzoline fell from a cart on to the road and, becoming fractured in the fall, poured a stream of highly inflammable fluid over the roadway and into the conduit of the electric tramway. It only required the sparks from the collector of a passing car to ignite the spirit, to cause a brilliant and dangerous conflagration. Luckily, however, the benzoline burned itself out in ten minutes, doing but little damage, though causing for the time being a considerable panic among the passengers of the ignited tramcar.

Electric Distribution of Time.—M. Henri Campiche, of Geneva, has devised a system of electric distribution of time, in which he has paid special attention to the simplification and cheapening of the distributor. By this means the inventor hopes to adapt his system to small local groups of clocks, as well as to extensive circuits. The distributor consists merely of an electrically-propelled pendulum, which actuates a pawl and ratchet wheel, and thereby causes an electrical impulse to be sent through the circuit every two seconds. The clocks are placed in parallel across a two-wire main. Simplification of the distributor may be desirable; but the question on which the system will stand or fall will be not simplicity but accuracy.

The Moving Sidewalk at Chicago.—One of the features of novelty in the Chicago Exhibition is the sidewalk or platform, which is maintained in constant motion, for the purpose of conveying visitors about the Exhibition grounds and buildings. It is interesting to notice the comparatively small amount of power which is required to keep this chain of platforms in motion. The dead weight of the entire train when unloaded is 500 tons, and the addition of the full complement of 4,000 passengers brings the load up to about 800 tons. We understand that not more than 105 E.H.P. is absorbed in moving this mass. The fact that a larger amount of power is unnecessary is undoubtedly due to the absence of stoppages—or, rather, startages—and to the low velocity of movement.

Electric Railway Tests.—The following figures relating to the Cedar Rapids (Iowa) Electric Railway may be of interest. The station plant consists of three Reynolds-Corliss condensing engines, three return tubular boilers, one 300-kilowatt, and two 80-kilowatt Thomson-Houston multipolar generators. The line is six miles long, with some $5\frac{1}{2}$ per cent. gradients. On August 3rd there were operated during the test two 34ft. double truck interurban cars weighing 20,000lb. each, equipped with two 50-H.P. T.H. motors each, one express car weighing 12,000lb. with the same equipment, and eight 16ft. cars weighing 9,800lb. each, equipped with one T.H. motor. The coal burnt was soft Iowa slack. The total car miles run during the test were 1,325, and the car miles run per ton of coal were 275.

The Chur Electricity Works.—The town of Chur is another addition to the many using Oerlikon dynamos, and it has the usual equipment of high-pressure alternators and transformers. Power is obtained from the falls of the River Rabinsa, where a head of about 220ft., supplying about 400 H.P., is available. There are at present some 3,000 8-c.p. lamps on, and a few arcs for public lighting, which have each their own transformer, and are thus entirely independent of one another. Motors are also in extensive use, and the Oerlikon non-synchronous type is generally used.

Digitized by Google

There is one motor of 100 H.P., and several of 1-9 H.P., the 100 H.P. motor being synchronous, and started by a small synchronous one. All the motors are on a special circuit. The station has been running since November, 1892.

Manganese Steel.—In a Paper read at the Chicago meeting of the American Institute of Mining Engineers, Mr. R. A. Hadfield gave some interesting information about manganese steel. A large magnet in the Edison laboratories, said to be capable of lifting nearly a ton weight, would not attract even a piece of manganese steel weighing but a few grammes. When manganese is present to only 9 per cent. the material is non-magnetic, taken in bulk, though its drillings are influenced considerably, thus indicating that to detach the material, or break it up into smaller masses, enables the magnetic force to exert its influence. This, however, does not apply, or only very slightly, to 13 per cent. drillings. Some years ago the writer noticed that some manganese steel car-wheels which had been running for a considerable period were, after their return, more susceptible to magnetic influence. It would seem that the constant vibration experienced by such articles had to some extent influenced the particular property under consideration. Manganese steel, when worked hot, can be reduced to the thinnest sections or drawn to fine wire (No. 32 B.W.G.). For this, however, great care is required; but ordinary gauges, to about No. 20 B.W.G., present no special difficulty. Messrs. Willans and Robinson, of Thames Ditton, have used 1½ ton of the manganese steel for resistance-coils in connection with a special electric plant.

Envermeu.—The little town of Envermeu, in the department of Seine-Inférieure, has an interesting electric light plant. The central station was commenced in September, 1892, and started running by November of the same year. Water power is employed to drive the dynamos, which are Gramme type machines giving 20 amperes at 300 volts at a speed of 1,020 revolutions per minute. These machines are used, partly to charge storage batteries, and partly feeding directly on to the supply mains. The storage cells are of the Verdier pattern, having each a weight of 15 kilogrammes, and a capacity of 10 ampere-hours per kilogramme. From the generating station an aërial line, consisting of three bare wires, conveys the power to the centre of the town, a distance of 1,200 metres, from which point a number of independent circuits radiate. The main conductors are of high conductivity copper, 6·3mm. in diameter (about No. 3 S.W.G.), and the middle wire is 4mm. in diameter (No. 8 S.W.G.). The station is designed to supply a maximum of 1,500 candles, or 150 glow lamps; and the load, which has now attained this value, is distributed in the following manner: there are six circuits of street lamps, each under separate control, amounting to 36 lamps; and the several circuits of private consumers' lamps make up the remainder. The rental of the former is at the rate of 25fr., and of the latter at the rate of 35fr. per lamp per annum; and the Supply Company undertakes house wiring at the rate of 25fr. per lamp.

Lightning and Gas Escapes.—During a recent visit at a summer hotel which was lighted by incandescent lamps, writes Mr. J. Trowbridge in a Paper in the *Phil. Mag.*, on "The Oscillations of Lightning Discharges and of the Aurora Borealis," I was much interested to observe that the lamps blinked at every discharge of lightning, although the interval which elapsed between the blinking and the peals of thunder showed that the storm was somewhat remote. This effect was doubtless due to induction produced by the surgings of the lightning discharges, for in heavy and in near discharges the lights were completely extinguished, although no fuses were burned. My observation of this effect of lightning upon electric light circuits also leads me to believe that the system of carrying electric light wires along gas-fixtures where both electric light fixtures and gas fixtures are combined is fraught with great danger. If there is any leakage of gas at the joints of the gas-pipes, or through a sand hole in the casting of the pipes, electric sparks, arising through resonance effects, or from the ordinary passage to earth of an electric charge brought into the building by the electric wires, can ignite the escaping gas and produce a mysterious conflagration. Such a conflagration was averted in the hotel in which I noticed the blinking of the lamps only by the careful scrutiny of an attendant, who noticed a jet of gas from a pinhole in the gas fixtures impinging on the woodwork. During the storm a minute electric spark had ignited the escaping gas. Electric light wires and gas pipes should never be contiguous, for no lightning-guard or protector can ensure that minute sparks, due in some cases to resonance effects, may not arise.

The Junior Engineering Society.—The annual general meeting was held last Friday at the Westminster Palace Hotel, the retiring Chairman, Mr. Sidney Boulding, M.I.M.E., in the chair. From the Council's report of last session, which was read by the secretary, Mr. Dunn, it appears that the Society continues to be well fulfilling the objects for which it was formed. The total membership now numbers 330, an increase of 13·4 per cent. during the session. It was stated that Mr. John Wolfe Barry had accepted the presidency for the ensuing session, 1893-4. Eight meetings had been held, and fourteen visits to works, &c., arranged, exclusive of the summer excursion to the West of England. The average attendance at the meetings was 56, and at the visits 65. The Society's premium had been awarded to Mr. R. W. Newman, Assoc.M.Inst.C.E., for his Paper on "The Sanitary Engineering of Dwellings." The balance-sheet showed receipts as £320. 19s. 4d., and expenses £306. 1s. 8d., leaving a credit balance of £14. 17s. 8d. On the motion of the Chairman, the report and statement of accounts having been adopted, and a vote of thanks passed to the retiring officers, various motions in reference to revision of rules were discussed. It was agreed that under certain circumstances the Council should have the power of remitting members' subscriptions; a system of compounding for subscriptions was also approved of. The election of officers and council for the ensuing session resulted as follows:—Chairman, Percy J. Waldram; vice-chairman, Henry J. Young; hon. librarian, H. B. Vorley; hon. auditors, F. W. Page, W. H. De Ritter; council, R. W. Newman, W. H. De Ritter, Harry Fraser, P. Marshall; remaining in office, P. G. Bowen, Basil H. Joy, Ernest King, Loftus Perkins; secretary and treasurer, W. T. Dunn.

Electricity and Vegetation.—At a recent meeting of the Physical Society of Geneva, a Paper was read by Prof. R. Chodat on "The Action of Electric Light on Vegetation." To discover whether germination was really quicker in plants under the influence of electricity Prof. Chodat made the following experiment:—A certain number of bean seeds were placed in water until the roots became visible. Fourteen seeds in all were used; they were divided into two lots, each of these being identically the same as regards weight, size, and appearance. Each lot was placed in a tub containing sawdust, and each was regularly watered, while the conditions of heat and light for each were identical. One of the tubs was then placed in communication with a Holtz machine, and was electrified, the first day for 40 minutes, the second for 2½ hours, the third day 3½ hours, the fifth day for 4 hours, and the following days for 3 hours up to the eleventh day. On the fourth day the leaves began to appear in the electrified tub, while no sign of a leaf was apparent in the other. On the fifth day the difference was still more marked, for the leaves and stems began to take an upright position, though no activity was manifest in the second tub. On the seventh day the non-electrified seeds began to put forth buds. A second series of experiments was conducted to ascertain the influence of electricity on the oxalis. Some specimens of this plant were placed in connection with the electrical machine, while some others were placed away from it. When the former lot had been electrified they were covered with a wooden box, which completely shut out the light. The second lot was covered in like manner. At the end of twenty minutes the two pots were examined; the electrified oxalis had kept their normal position, while the other plants were in a drooping condition. The same effect has been tried on this plant at the end of the day. When twilight came on one pot was electrified, while the other was not. Soon the difference became apparent, for the plants in the first pot remained awake till long after the other had closed its buds. It is an interesting fact that the sensitive plant is not affected by these electrical influences.

AN EXAMINATION OF PROF. LODGE'S ELECTRO-MAGNETIC HYPOTHESIS.

BY PROF. J. H. POYNTING.

(*Concluded from page 608.*)

I have now given an account of the main features of Dr. Lodge's hypothesis as to the nature of electric charge, magnetism, and current, and I have done this at considerable length because I propose to discuss the foundations for the hypothesis, and to see if they are sufficiently firm to bear the superstructure. To recapitulate the main features, we have a double ether consisting of equal + and − portions attached in some sort of way to matter as a framework—elastically in dielectrics—loosely, with a kind of viscous connection in conductors. The two ethers always move in opposite directions along the lines of electric force, and in dielectrics they store energy by their displacement past the material framework, while in conductors they only dissipate it during the displacement. The ethers are cellular in construction, and the cells are capable of rotation, this rotation constituting magnetism, and the accompanying rotational energy being magnetic energy. The axes of rotation are along the lines of magnetic force. The cells roll on one another as if quite rough in dielectrics, and as if lubricated with viscous oil in conductors, and they are alternately + and −, and moving in opposite directions, a clockwise moving + cell giving the same direction to the magnetic force as a counter-clockwise - cell. Current is, according to Lodge, slip of these cells against each other, but according to the interpretation I have given of his theory, current is a double and continuous procession of the cells in a conductor, with the consequent rotations.

The hypothesis is avowed by its author to be an attempt to obtain a mechanical explanation of electric and magnetic phenomena. He uses the main idea of Maxwell's well-known model, but replaces Maxwell's duality of magnetic wheels and electric "idle" wheels by a duality of electric wheels. It is, perhaps, open to question whether this is really a simplification, but the attempt was very well worth making, for it is only by variation and natural selection that the mechanical model will be suited to its environment in the electric world.

It is, I suppose, useless to look for any other than a mechanical hypothesis as final. Probably because we are able to picture mechanical processes, able to think of ourselves as seeing what goes on, seeing kinetic energy manifested in the moving parts, able to think of ourselves as part of the connecting machinery, feeling the stresses, and helping to make the strains, we have come to regard mechanical explanations as the inevitable and ultimate ones.

Thus, though the old mechanical hypothesis of light is for the present discarded in favour of an electromagnetic one, I suppose no one is content with the present position; but we are all looking forward to the time when, by mechanical explanation of electromagnetism, light shall once more become mechanical. Nevertheless, it is well to bear in mind that all such explanations are merely hypothetical, and may at any time have to be discarded, as the solid ether light hypothesis has been discarded. Indeed, they are solely of value as a scaffolding enabling us to build up a permanent structure of facts, *i.e.*, of phenomena affecting our senses. And inasmuch as we may at any time have to replace the old scaffolding by new more suitable for new parts of the building, it is a mistake to make the scaffolding too solid, and to regard it as permanent and of equal value with the building itself. It is on this point that I find most cause for disagreement with Prof. Lodge. He appears to me to regard his hypothesis as inevitable and permanent, or at least as approximating to the permanent and inevitable. The scaffolding, in fact, is made as important as the building. It behoves us, therefore, to examine into the security of its foundations.

We may take the hypothesis as based on two statements:—

I. Regarding electricity at rest, "Whenever we perceive that a thing is produced in precisely equal and opposite amounts, so that what one body gains another loses, it is convenient and most simple to consider the thing not as generated in the one body and destroyed in the other, but as simply *transferred*" (p. 9).

II. Regarding electricity in motion: "Magnetism is nothing more nor less than a whirl of electricity" (p. 171).

Let us examine some cases which should come under the first statement.

We may regard the upper and under surfaces of a vessel of liquid as respectively positive and negative, and if we measure them by their projections on a horizontal plane they are equal and opposite element by element. We clearly cannot create a positive without an equal negative. Bring the two elements together, and they neutralise each other, for both cease to exist. We have no idea here of something transferred.

Or, take the case of a rotating cord. Its two ends, as viewed from the outside, have equal and opposite properties, as may be seen at once if we think of them as brought close beside each other. If the rotations were transferred to one and the same body the net result both to themselves and to the body would be no motion. Or if the cord were cut away in slices, bit by bit, when it is all cut away the two ends have come together, and have, in a sense, neutralised each other. Here again we think of nothing transferred.

As a third case take a magnet. We always create equal and opposite poles at the same time with mutually neutralising properties, and to bring this within Dr. Lodge's statement we have only to consider the magnet as made up of two bodies joined together in the middle. Or perhaps we might take the case of the creation of N. and S. poles by the breaking of a magnet. No one has yet made a displacement or transfer hypothesis for magnetism except for the purpose of illustration. This, by the way, is rather remarkable, for magnetism with its re-entrant tubes of induction is so much more ready to lend itself to such a hypothesis. We seem to have finally made up our minds that electric is strain energy, and that magnetic is rotational energy, and we do not even consider the alternative of magnetic as strain and electric as kinetic energy. No doubt the existence of magnetic rotation of the plane of polarisation of light strongly suggests the rotational nature of magnetism, but we can hardly claim any explanation of the phenomenon yet put forth as complete, and certainly none is exclusive. The other facts would possibly be equally well explained if we thought of electric tubes of induction as strings of wheels with their spindles along the axis of the tubes, and magnetic tubes as lines of flow of ether or of two ethers, with a certain displacement coefficient, greater in diamagnetics, less in paramagnetics. I do not put this forward as worth following out, but merely to illustrate the contention that we need not necessarily think of + and − electrification as due to a longitudinal transfer of something. It appears to me quite possible then to symbolise the positive and negative charges facing each other across a dielectric in other ways than by the transfer of something from one towards the other.

Turning now to the second fundamental idea, Ampère's hypothesis, that a magnetic molecule is a small closed electric current, this is really closely connected with the idea that there is something moving in the direction of an electric current and constituting the current. It is in fact dependent on our acceptance of the first idea. For consider what an Amperian current is phenomenally. There is no resistance, and therefore no heat developed, and no fall of potential; there is no junction, and therefore no Peltier effect; there is no break, and therefore no chemical effect. The one effect left is the magnetic one. If, then, we take away the idea of some substance whirling round and round in a channel, all that we have left is a little permanent magnet. In other words, we explain the constitution of a magnetic molecule by supposing that it is a molecule having a magnetic constitution.

It is true that if we get a bundle of lines of magnetic force and tie them together with a perfectly conducting cord with its ends joined up we have a permanent magnet, for no more and no less lines can pass through the ring of perfectly conducting stuff. But this does not really explain. It does not show that the unknown is a case of the known. For a perfect conductor is far more difficult to think of than a permanent magnet.

Digitized by Google

It is getting time that these so-called "perfects" were abolished from Physics. We have to deal with matter as it is and not as we should have had it if we had been consulted as to how it should be made in order to simplify our equations. The perfect gas has nearly gone and I shall be glad to see the perfect conductor preparing also to depart.

If, however, we grant substantiality to the electric current, we are met by a difficulty in connection with Ampère's hypothesis which, at any rate, requires examination.

Let us suppose that we have a circuit of self-induction L and resistance R, and let N be the number of outside lines passing through the circuit. If E is the E.M.F. of the battery kind in the circuit the current equation is

$$E - \frac{d}{dt}(L\,C). - \frac{d\,N}{dt} = C\,R.$$

If $E = 0$ and $R = 0$ we have an ampere circuit for which

$$\frac{d}{dt}(L\,C) + \frac{d\,N}{dt} = 0,$$

or

$$L\,C + N = \text{constant}.$$

In words, the total number of lines of force threading the circuit is constant.

If, now, N increases, either L or C must diminish. In order that L may diminish the circuit must contract and pinch in, as it were, the lines of force. But meanwhile, since the total is constant, the number of lines passing through the same area is increasing, and we should expect the spin, therefore, to increase and tend to make the tubes of force widen out. That is, there would be resistance to the contraction. The contraction is contrary, too, to our ordinary experience of a circuit with a current in it, for such a circuit tends to expand. If, on the other hand, the circuit is rigid, L is constant and C must diminish. If, as I gather from the general tenor of Dr. Lodge's work, the ampere circuit is one of the ether cells peculiarly constructed or at least of the same order of magnitude, a diminution of C means a diminution of spin of this cell. But the total number of lines of force through it is constant, which seems to imply that the spin remains the same. This seems to force us to suppose that the ampere circuit is *not* of the order of the ether cells, but larger, so that it may include within its contour a number of these cells. Then when N increases, C round the boundary may diminish, and still $L\,C + N$ be constant, for the internal wheels may be spinning at the same rate as before, but the external wheels more slowly, the current being a function of their difference. It would require further examination to see whether the total spinning energy could thus be accounted for. At first sight it would appear that that energy is diminished by the lessening of C just when we want it to increase.

If we are to suspend our judgment as to the substantiality of electricity, and are not as yet to conclude that a current is a rushing round of a thing of some kind, we are bound also to suspend our judgment as to Ampère's hypothesis, and if we are in this state of suspense, and, for my own part, I must confess to being so, Dr. Lodge's hypothesis and its accompanying models are to be used rather as illustrations—as analogies—than as ultimate solutions. For the purpose of illustration they are of the greatest value. Like a bank reserve, ready in case of emergency to cash the symbolic bank-note, they are in the background in the mind ready to turn into mechanical reality the ordinary electromagnetic symbols, such as lines of force, which are, I think, much more easy to deal with, but which are, doubtless, wanting in reality.

Perhaps Dr. Lodge may consider that my criticism is somewhat carping, in that I have nothing constructive to put in the place of the hypothesis to which I object. But I believe that the time has hardly come for ultimate mechanical construction, and that at present progress is more likely to be made if we are content with an electromagnetic explanation, if we merely carry down to the molecules and their interspaces the electric and magnetic relations which we find between large masses and round large circuits, and leave the ether out of account. I believe that we may symbolise electric and magnetic actions by means of lines of force and their motions in a way which allows us to think clearly of the phenomena, and though the ultimate nature of the lines of force is unknown, we can only say the same of the ether. In the application of these lines of force to the molecules, and their constituent atoms, there appears to be hope for some kind of explanation of the chemical phenomena of the circuit and of the distinction between electrolytic and metallic conduction. The difficulties in the way are by no means small, as everyone knows. I may, at some future time, attempt to set forth some of the difficulties as they occur to me, in the hope that a plain statement of them may lead some reader to help in their solution.

PRIMARY BATTERIES IN THEORY AND PRACTICE.*

PART I.

BY W. R. COOPER, M.A.

Like many other great discoveries, the voltaic cell was the result of mere chance, due, indirectly at least, to the dead frogs of Galvani. The theory which Volta framed in explanation of the observed phenomena led him about twenty years later, in the year 1800, to construct his voltaic pile, and also the "crown of cups," or the voltaic element in its simplest form. Cruickshank (in 1801), Wollaston (in 1815), and Hare (in 1822) introduced various forms which were only slight modifications of Volta's cell. In 1830 Sturgeon discovered the value of amalgamating the zinc plates, but it was not until 1836 that any great improvement was effected, when Daniell and Grove brought out the respective cells which are still known by their names. Six years later Bunsen introduced the carbon element in a practical form, and, after the lapse of another twenty-six years, the Leclanché battery appeared in 1868.

Having briefly glanced at the history of the subject, let us now turn to a few points in detail.

Constitution of the Voltaic Cell.

The first question that suggests itself is:—What are the essential constituents of a cell? Experience points to the conclusion that at least three elements are necessary, one of which must be a conductor, and one an electrolyte, the third belonging to either class. It is further necessary that two of these elements should be capable of chemically acting upon each other.

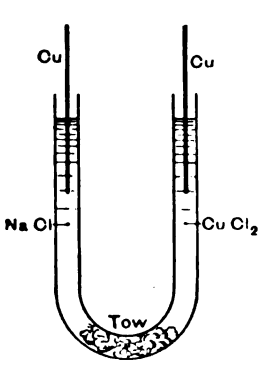

Fig. 1.

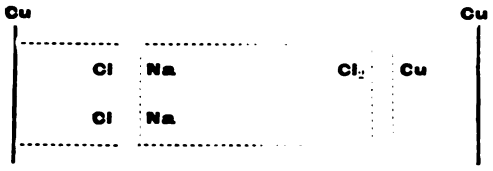
Here we must distinguish between two possible modes of chemical action. A chemical change may take place (1) such that the energy liberated is exerted wholly at the spot where the reaction occurs; or (2) such that the energy is transferred elsewhere, and is there capable of utilisation. The first includes ordinary chemical combination; the second is that which is essential to the voltaic cell. For example, if impure Zn is immersed in dilute H_2SO_4, $ZnSO_4$ is formed, and hydrogen is evolved: energy is given out, but it is not transferred. If a strip of copper is also immersed in the acid, and the external circuit completed with the zinc, a larger quantity of $ZnSO_4$ is formed, and hydrogen is evolved at the copper as well as at the zinc: here there are two portions of energy, the one being

* Paper read at a Students' Meeting of the Institution of Electrical Engineers, May 19th.

Digitized by Google

transferred and the other not transferred. If, now, the zinc is amalgamated and joined up to the copper, the whole of the energy given out is transferred, and the useless energy is avoided.

In the batteries that are usually employed the cells consist of two conductors and one or more electrolytes. But, as far as current is concerned, one metal and two electrolytes will give the desired result. For example, a cell may be formed by a U tube, one limb containing NaCl, and the other $CuCl_2$ (separated by tow, as shown in Fig. 1), the plates being of copper. The copper reacts upon the NaCl to form cupric chloride, and the liberated sodium reduces the cupric chloride in the other limb, copper being deposited on the copper plate as indicated below :—



The cell just described depends for its action upon the decomposition of one of the electrolytes by the metal. Becquerel's cell is often given as an instance of the production of current by the interaction of two electrolytes. A porous pot filled with HNO_3 is placed in an outer vessel containing KOH, platinum plates being used for both the poles. The production of the current will be discussed later on in this Paper.

It is hard to give anything like a complete definition of a cell. In all probability the solution of every metal is accomplished by voltaic action, the third element being obtained either by impurities in the metal itself, or by the solvent acting in two capacities at the same time.

Seat of the E.M.F.

The origin of the E.M.F. in the voltaic cell has given rise to many ingenious hypotheses, and has formed the subject of hot scientific warfare, which is not altogether at an end. We need here only consider the contact theory, or that of Volta, in which the contact of dissimilar metals is supposed to be the seat of the E.M.F., and the chemical theory, in which chemical action alone is said to be the acting force. At first sight it appears strange that two such entirely different theories should survive; but the intrinsic difficulty of experiment is so great, that it is very hard to find a test which shall decide between the two.

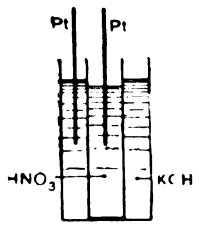


Fig. 2.—Becquerel's Cell.

In studying the phenomena which Galvani observed with his frogs, Volta found that the same convulsive movement could be obtained by the contact of two dissimilar metals, and he consequently referred the action to the junction of the two metals. This led him to construct his well-known pile, consisting of Zn, Cu and wet cloth. He also found that he could arrange the metals in a series, such that any one of them assumed a positive potential when in contact with a metal lower in the series; and that the potential difference, resulting from any number of metals connected together in series, is the sum of the differences due to the several contacts, and is also equal to that between the extreme metals. From this it follows that there can be no resultant E.M.F. in a closed ring of dissimilar metals, provided the junctions are all at the same temperature.

The contact force of dissimilar metals has been measured by a large number of physicists, generally by means of a condenser, the plates of which are made of the metals in question. These are placed parallel to each other at a small distance apart, and simultaneously touched with a wire of the same metal as one of the plates. The capacity is then diminished by separating the plates, and the deflection on an electrometer connected to one of them is a measure of the force. This is briefly the method employed by Kohlrausch.

The force of contact between metals and liquids has also been measured; but all these experiments must be received with a certain amount of caution, for the simple reason that we are uncertain as to what is really measured. No proof has been given of the existence, or non-existence, of force of contact between air and metals, or air and liquids. Such investigations, therefore, involve an unknown quantity which may vitiate all the results obtained.

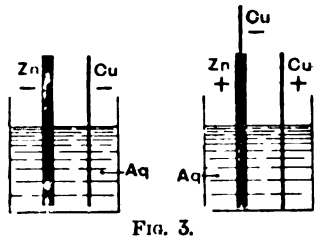

Fig. 3.

Lord Kelvin has given an elegant proof of the force of contact between dissimilar metals. A needle of thin sheet metal is suspended just above a circular plate made half of zinc and half of copper, so that it forms a radius to the plate, and lies initially in the direction of the diameter formed by the junction of the two metals. If the needle is charged positively it deflects towards the copper, the deflection being reversed if it is charged negatively, thus showing that there must be an E.M.F. of contact, the zinc being positive to the copper.

Nevertheless, these forces of contact do not appear to be as definite as could be desired. The results depend, to some extent, upon the nature of the surfaces employed. The theory is still less satisfactory when we consider the contact forces of liquids, or of liquids and metals. These cannot in general obey Volta's law, or there would be no E.M.F. in the ordinary cell. They have been measured in some cases, but they do not form a consistent series with the metals.

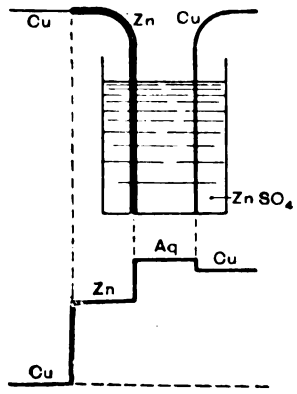

Fig. 4.—Potential Difference Diagram for Simple $ZnSO_4$ Cell.

In the simplest form of galvanic cell we have three contact forces to consider. Those due to either metal and the electrolyte may or may not cancel. For example,* if zinc and copper are immersed in water they are reduced to the same potential, and both are negative to the water (*see* Fig. 3). If, now, a piece of copper is attached to the zinc, the former becomes negative, while both the zinc and the immersed copper become positive, being maintained at the same potential by the water. The E.M.F. is simply that due to the Zn and Cu, the remaining contact forces cancelling.

But if $ZnSO_4$ is employed instead of the water this is not so. Here the

E.M.F.	$Cu - ZnSO_4$	$= -0{\cdot}113$ volt
,,	$ZnSO_4 - Zn$	$= +0{\cdot}358$
or electrolytic contact forces		$= +0{\cdot}245$
If that of $Zn - Cu = 0{\cdot}75$, then E.M.F. of cell		$= 0{\cdot}995$

* Fleeming Jenkin, "Electricity and Magnetism."

Digitized by Google

Hence it is erroneous to suppose that the E.M.F. of a galvanic cell is given simply by the contact force of Zn – Cu. A potential difference diagram may be constructed as shown in Fig. 4, which is reproduced.

Volta's theory does not appear to have been strongly opposed until about 1830, when Faraday conducted a large number of experiments to test its correctness. He came to the conclusion that chemical action (decomposition as well as combination) is essential to a galvanic cell, and enunciated the law which bears his name, viz.: The decomposition which occurs in electrolysis, or in a galvanic cell, is perfectly definite, and is a measure of the total quantity of electricity passing round the circuit. He was thus led to think that the current was due simply to chemical action. It appeared unreasonable that the E.M.F.s of contact in a metallic circuit should be so balanced as to give no resultant, whatever the arrangement; and that electrolytes should either exert no contact force, or, if they do, that they should not be subject to the same law as the metals. It was found that no current was obtained if an electrolyte were employed, having no chemical action on either metal, even though in itself a comparatively good conductor; and Faraday, therefore, concluded that a current cannot be due to E.M.F. of contact. But we now know that no current could have been obtained under these circumstances without violating the law of conservation of energy: no energy is supplied to the circuit, and therefore none can be obtained from it. This test, therefore, fails to prove the point.

The truth in this case probably lies between the two theories. As Fleeming Jenkin observes: "The opponents of contact electricity denied and falsely explained things now known to be true, and the original supporters of the contact theory were ignorant of dynamics. . . . Perhaps it is accurate to say that the potential difference is produced by contact, and the current maintained by chemical action." Be this as it may, much remains to be proved.

Let us now turn from this somewhat unsatisfactory part of the subject to the consideration of two defects which soon became apparent in the voltaic cell, viz., local action and polarisation.

Local Action.

Local action, or loss through voltaic circuits on the positive plate, received no check until Sturgeon introduced, in 1830, the remedy of amalgamation which has not been superseded. The mercury is often said to act mechanically rather than chemically, the protection being afforded by a film of hydrogen which prevents the liquid from coming in close contact with the amalgam. Thus amalgamated zinc is unacted upon by dilute H_2SO_4, but, if a little HNO_3 is added, the hydrogen is removed by oxidation, and the zinc dissolves. This, however, is no proof of the assertion. The HNO_3 simply forms a voltaic cell in the manner hereafter considered.

It is a curious fact that the zinc has its properties but slightly changed by amalgamation. It is found that if amalgamated zinc and mercury are employed for the metallic elements, as in a Clark cell, the E.M.F. is practically unchanged, whether the percentage be large or small of mercury in the amalgam. In the case of the Daniell cell the E.M.F. is sometimes stated to be increased through the amalgamation by 0·13 volt.

Unfortunately, this remedy for local action cannot be applied to other metals. We are, therefore, restricted to the use of zinc for the positive plate, at least for acid batteries.

(*To be continued.*)

LAMP-HOLDERS.

The carbon glow lamp had not been invented many months before a holder was found to be necessary. It was natural that Edison should have been the first to design and to patent such an arrangement, for from the beginning, long before a practicable lamp had been discovered, he was arranging for mains, meters, switches, and a score of details by which electric light might be introduced into daily life. In his patent No. 578, of 1880, to which we shall refer again, he says: "As a necessary part of any practical system of electric lighting for domestic uses it is essential that the electric lamp should be simple in construction and complete within itself, requiring no skill in placing in position or in manipulating it. . . . A cup-shaped holder is made of insulating material, ornamented as desired, the bottom being fashioned so as to be secured in any suitable support, such as a bracket or chandelier. . . . The main conductors may pass to the holder through ordinary gas or other tubing, and through the bracket or chandelier arm or in any other suitable way." It was reasonable to guess at this early date that lamp-holders would be ornamented, but up to the present day this is almost unheard of, in spite of the ugliness of most patterns.

The lamp-holder question begins to acquire a new importance at the present time, since several lamp-holder patents still remain in force, and the more important of them are the property of the Edison and Swan United Electric Lighting Company. It is well known that this Company makes lamp-holders, and at the same time grants licences to other manufacturers. The terms of these licences it is beyond our province to discuss; suffice it to say that a considerable number of lamp-holders are made by the licencees, who thus compete with the proprietors of the patents. The patents under which licences are granted are the following:—

Edison, No. 578, February 10, 1880,	expiring	February, 10, 1894.
Swan, No. 5,702, December 28, 1881,	„	December 28, 1895.
Johnson, No. 1,094, March 7, 1882,	„	March, 7, 1896.
Dornfeld, No. 2,285*, January 28, 1884,	„	January 28, 1898.

Besides these patents we may allude to a few other early lamp-holder patents which are not included under the ordinary licence. These are:—J. W. and C. Swan, No. 4,390, 1882; A. Swan, Nos. 2,528, 1883; 5,153, 1883; 6,319, 1884; 9,185, 1884; 15,025, 1884; H. Pieper, 4,854, 1885.

Edison's patent, No. 578, 1880, for "Improvement in electric lamps, and in the method of manufacturing the same," contains 17 claims. The majority of these relate to the manufacture of the lamps; some of them are singularly wide. For example: the seventh claims "An incandescent conductor formed of a single carbonised fibre substantially as described." The claims relating to the subject at present under consideration are the ninth to the seventeenth inclusive, which are as follows:—

Ninth.—A separate electric lamp, adapted to be readily removed from or placed or replaced upon or within a suitable holder, substantially as herein described.

Tenth.—The combination of a separate removable electric lamp and a suitable holder, substantially as herein described.

Eleventh.—The combination of a separate removable lamp, a suitable holder, and electric conductors, which complete the circuit when desired to said lamp, but are not attached thereto, substantially as herein described.

Twelfth.—An electric lamp, consisting of a glass globe, substantially of one piece of glass hermetically sealed, and enclosing in a vacuum material capable of being rendered incandescent by an electric current, and provided at its base with contact pieces, substantially as herein described.

Thirteenth.—The combination in an electric lamp of a glass globe enclosing in a vacuum material capable of being rendered incandescent by an electric current, an insulated base, spring contacts, and conductors therefrom to the incandescent material substantially as herein described.

Fourteenth.—A socket or holder for electric lamps consisting of an insulating cylinder, formed to receive and support the lamp, and provided with two contact plates and a circuit controling device for controling the circuit to one of the contact plates, substantially as herein set forth.

Fifteenth.—The combination with a bracket or chandelier arm of a socket or holder adapted to receive and support an electric lamp, substantially as herein set forth.

Sixteenth.—The combination of a holder, bracket or chandelier arm with a socket or holder adapted to be received thereon, and to receive and support an electric lamp and conductors passing through the arm to contact plates in the holder, substantially as herein set forth.

Seventeenth.—The combination with a socket or holder provided with suitable contact plates of a lamp provided with corresponding contact springs upon its exterior, substantially as herein set forth.

The specification is illustrated by 13 figures.

The ninth, tenth and eleventh claims with their curious legal redundances contain the gist of this master patent. The licencees who work under this patent, and who, we presume, have thus acknowledged its validity, concede to Edison the grand invention not only of a lamp-holder, but of all lamp-holders.

If it may have seemed that we have ever failed to appreciate Edison's scientific work, we are ready to acknowledge, in cases of which this is an example, his marvellous foresight and

Digitized by Google

shrewdness, it may be said that anybody who believed in the possible future of lighting by glow lamps would naturally have conceived the idea of a lamp-holder and a detachable lamp, but as a matter of fact Edison seems to have been the first to have formed this conception, and looked forward with all the confident visualisation which has characterised his work to a "practical system of electric lighting for domestic uses."

Contact pieces provided in the base of the lamp are alluded to in the twelfth claim, and in the thirteenth it is suggested that the base should be insulated, and that the contacts should be "spring contacts." The fourteenth claim, relating to the holder or socket, speaks of contact plates, and suggests the use of a switch. The seventeenth claim also suggests that the holder should be provided with rigid plates, while contact springs should be provided on the exterior of the lamp; these are shown in Fig. 12, which we reproduce. These claims for metallic contacts on an insulated base of a lamp, seem to be of considerable importance.

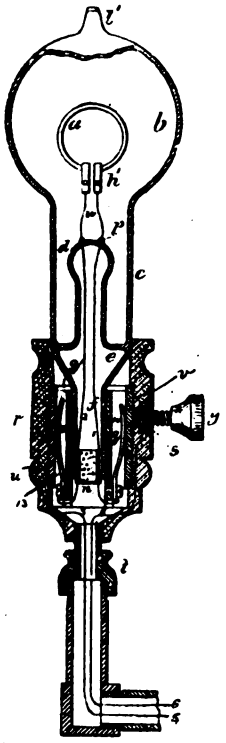

Fig. 12.
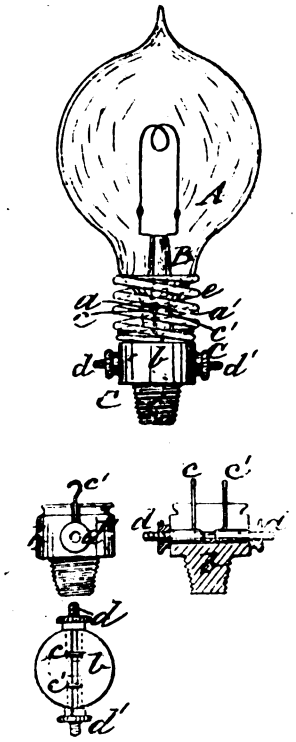
Reproduced from Edison's Specification No. 578, 1880.



Figs. 1 and 2.
Reproduced from Swan's Specification No. 5702, 1881.

Mr. J. W. Swan's first patent, 5,702, 1881, the second one of the licence, is a step backwards. We find described in the most minute detail the lamp with platinum loops and a holder with hooks. The specification begins thus :—

"My invention relates to improvements in sockets or holders for electric lamps, whereby a lamp without any external fittings can be readily attached to the conducting wire, and a good contact between them and the terminal hooks or eyes of the lamps can be effected and maintained."

Nothing could be more distinct from Edison's proposal to attach springs, and other metallic parts, to the base of his lamp than these simple contrivances of Mr. Swan, which are still to be found in some old-fashioned examples of electric lighting at the present day. In the course of his specification he suggests concentric contacts, and a system of concentric wiring is described. The system of rigid hooks and a spiral spring, as well as spring hooks is described. With the exception of the one provided with concentric wiring, the lamp-holders described in this specification are made with outside terminals. The following is his first claim.

First.—The employment of sockets or holders adapted to incandescent electric lamps without external fittings, and so arranged that efficient electrical contact is made aud maintained between the hooks or their equivalents of the socket or holder and the lamp terminals by the outward push of a spring interposed between the lamp and the lamp socket or holder, or by the act of screwing or sliding towards the lamp an external tube substantially, as hereinbefore described.

The second claim relates to details.

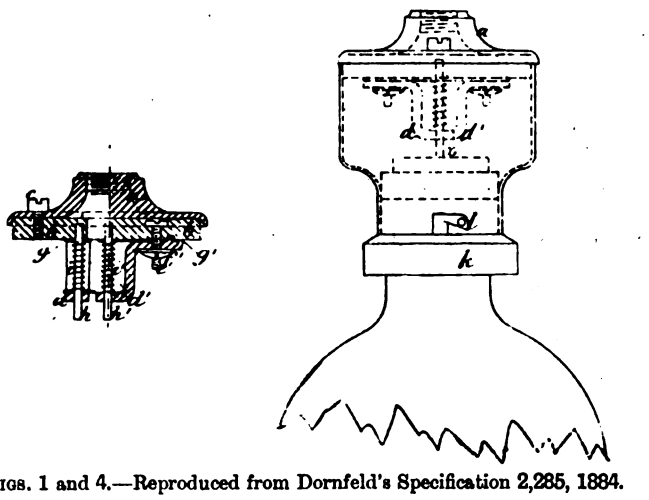
The fourth patent is that of Mr. E. H. Johnson, No. 1,094, 1882. The inventor is described as of Holborn-viaduct, in the City of London. The specification is very short, and contains only two claims. It very clearly describes the well-known Edison socket, with the coarse taper screw of thin metal, closely resembling the Edison socket which is in common use to-day. We understand that this socket was the invention of Edison, although his name does not appear in the specification.

After an interval of nearly two years, during which time no doubt many improvements were made in lamp-holders, Carl Dornfeld filed his patent, No. 2,285, 1884, for "Improvements in Holders for Incandescent Electric Lamps." Although a complete and very efficient lamp-holder is described in this specification, the pith of the patent is for "an arrangement of spring pins with guides." A lamp-holder with two large spiral or volute springs placed concentrically is illustrated and described, but the spring pins form the essential feature of the patent. The original specification contains four claims; the first two are as follows:—

First.—In holders for incandescent electric lamps the arrangement of spring pins with guides, which effect both the electrical contact with the lamp, and, by means of their vertical pressure against the lamp head, the secure fastening of the lamp in the holder, substantially as described with reference to Figs. 1 and 4 of the drawings.

Second.—The special arrangement of a holder for incandescent electric lamps with metal plate, insulating disc, guides, spring pins and metal casing, substantially as described with reference to Figs. 1, 2, and 4 of the drawings.

The third claim is for a modification, and the fourth claim, which was cancelled by amendment on February 6, 1890, related to the use of an insulating head-piece, an incandescent



Figs. 1 and 4.—Reproduced from Dornfeld's Specification 2,285, 1884.

electric lamp having on its circumference two diametrically opposite studs, and on its flat surface two small metal plates insulated from each other in connection with the wires from the carbon filament. We do not presume to explain the reasons for which this amendment was made, but it is clear that the metal plates which Edison proposed to affix to the sides of the stem of his lamp were substantially equivalent to the metal plates claimed by Dornfeld.

With the slight modification of mounting the spring contacts in tubes, forming the well-known buffer contact to be found in modern lamp-holders, this patent contains all the essentials of this extremely convenient and indeed indispensable device. In the body of the specification the lamp-holder is described as consisting of a disc of insulating material upon which are fixed a pair of Z brackets. The illustrations, however, two of which we reproduce, show a pair of small metal plates bent at right angles.

(To be concluded.)

MODERN VIEWS OF ELECTRICITY.

The concluding portion of Prof. POYNTING's examination of Dr. OLIVER LODGE's electromagnetic hypothesis, which we print this week, is perhaps the most interesting, as well as the most original, of the three into which it has been divided. In a critical examination, originality is not to be looked for, but from a good criticism it is rarely absent. Cautious as are the leaders in Physical Science in giving their vaguer speculations, as Prof. POYNTING has told us, fearing that their weaker followers will distort their views; still more reluctant, perhaps, are they to examine in so careful a manner as Prof. POYNTING has done, the general hypotheses of any one man, although they will readily discuss separate parts of his work. A great debt of gratitude is owed not only by scientific men, but by the intelligent public to Dr. OLIVER LODGE for his "Modern Views of Electricity." Nobody else has ventured to collect hypotheses of the nature of electromagnetic science and to add to what has been drawn from others, a wealth of original speculation, but more than this, Dr. LODGE has been able for the most part to divest the subject of many of the difficulties which surround it, and avoiding mathematical language where most men would have no other treatment to offer, he has succeeded almost in removing even the appearance of abstruseness. But in reality his book is, as Prof. POYNTING has observed, by no means the easy reading which the absence of mathematical treatment might lead us to expect. Dr. LODGE has recently remarked upon the evils of being too explicit, and observed that the beauty of mathematics is that it is so vague; with what admirable care, then, has he rejected the easy method of ambiguity and has confined himself to simple English

Digitized by Google

"The method which has been for the most part employed in conducting such inquiries," said MAXWELL at a lecture before the Chemical Society, "is that of forming an hypothesis, and calculating what would happen if the hypothesis were true. If these results agree with the actual phenomena, the hypothesis is said to be verified, so long, at least, as some one else does not invent another hypothesis which agrees still better with the phenomena. The reason why so many of our physical theories have been built up by the method of hypothesis is that the speculators have not been provided with methods and terms sufficiently general to express the results of their induction in its early stages. They were thus compelled either to leave their ideas vague and, therefore, useless, or to present them in a form, the details of which could be supplied only by the illegitimate use of the imagination. In the meantime the mathematicians, guided by that instinct which teaches them to store up for others the irrepressible secretions of their own minds, had developed with the utmost generality the dynamical theory of a material system."

Hypothesis, then, is a kind of imaginative garment with which we clothe our ideas. MAXWELL does not tell us on what grounds one hypothesis may be said to agree better with the phenomena than another, but of two hypotheses, both of which exhibit an equal agreement, that one is to be preferred which is the more simple; and when by successive additions to observed phenomena, an old hypothesis has to be patched and trimmed, and, to retain the metaphor, to be let out, to fit the whole body of facts, it is worth considering whether a new coat should not be made, and of more modern material. On the other hand, of two equally simple hypotheses that is the preferable which includes a rational explanation of the greatest number of phenomena; or, to be more exact, which gains the highest number of marks when to each phenomena which it explains there is attached a suitable figure indicating its importance. Simplicity alone, however, is not by any means the chief merit of a hypothesis. The well-worn hydraulic analogue is an example. Invaluable in the law courts and amply accurate for popular science in magazines, it presents ideas in a form, the details of which are supplied by an illegitimate use of the imagination. It is well that mathematicians should continue to store up the secretions of their minds well in advance of busy experimenters and speculators, who, when the one have got together a sufficient number of phenomena and the other a brood of larval hypotheses, may turn to mathematicians for nutriment, which will result in the production of a well developed theory.

So long as we were content with a solid elastic ether with a rigidity of 842·8 and a density of $9{\cdot}36 \times 10^{-19}$, as described by MAXWELL in the "Encyclopædia Britannica," the connection between electromagnetic and optical phenomena promised to become clearer year by year; and some of those who neglected to follow the various modifications which had been found necessary were disappointed to find that HERTZ'S researches had not settled the whole matter, and bound up the sciences of electricity and optics into one coherent unity. While the hypothesis of ether has become more and more intricate, the comparatively simple mechanical illustration of MAXWELL'S wheels and idle wheels has, in the hands of Dr. LODGE, been developed into a system of considerable complexity, and so far from being complete his hypothesis of the nature of electricity is only offered as the starting point of a hypothesis of magnetism—"Magnetism is nothing more or less than a whirl of electricity." Commenting on this, Prof. POYNTING turns to the Amperian hypothesis of magnetic molecules which owe their magnetic properties to a small closed electric current, and so many difficulties arise when criticised from a modern standpoint, that, useful as it has been in the past, many of our readers will feel that they can scarcely content themselves with suspending judgment on it, and remaining, as Prof. POYNTING confesses he must, in this state of suspense. We can part as Prof. POYNTING asks us from "perfect" conductors without a pang, and bid adieu to the Amperian molecule, and wish that physicists would, as he suggests, deal with matter as it is and not as we should have it if we had been consulted as to how it should have been made in order to simplify our equations. But we must not forget that while, on the one hand we sacrifice ideal matter in order to develope the fulness of our mathematical truth, we are equally called upon on the other hand to seek to devise some consistent material explanation in order to convert the mathematical expression to which we are led, into a physical truth. While he almost apologises for his criticism of Dr. LODGE'S views on the ground that he has nothing constructive to put in the place of the hypothesis to which he objects, Prof. POYNTING, in his last paragraph, suggests that progress is likely to be made by leaving ether out of account for the present, and by considering the electric and magnetic relations of molecules as those of large masses.

In a leading article on November 21, 1890, commenting on a communication from Dr. OLIVER LODGE on the transfer of energy by the ether, we protested against the doctrine of materiality of electricity. "There are only two things going," we quoted from Mr. OLIVER HEAVISIDE: "Matter and Energy; nothing else is a thing at all; all the rest are Moonshine, considered as Things." Electricity, we pleaded, is but the name for an agent which appears to underlie a certain group of phenomena, just as caloric was a very useful name, and was used to connote a similar agent which was supposed to appear and disappear by transference from one body to another. In another leading article on December 18, 1891, after objecting to the coulomb as an ancient residuum of the fluid theories of electricity, we suggested that it is more easy to conceive that a molecule is a minute magnet than to contemplate the Amperian hypothesis that magnetism is due to the circulation of molecular electric currents, and that if it be granted that every molecule is a magnet it is only necessary to move it in order to produce both electromagnetic and electrostatic phenomena. Why, then, we asked, do we need the idea of something called electricity, and that lumps of it should be measured in coulombs? We hope that the simple mode of thought which Prof. POYNTING recommends, may, by ignoring for the time an artificial structure of an unknown medium, lead not only to a rational understanding of electromagnetism, but to the solution of the profound problem of the structure of ether.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Continued from page 612.)

The author has adhered to the expression "watts per candle-power" in preference to that of "candles per watt," as, although the latter is the more correct, the former has the advantage of being the one generally adopted, doubtless because it is more convenient. It is easier to quickly grasp the meaning of a certain number of watts, and perhaps a fraction added, than of a particular fraction of a candle-power.

It will be readily understood from what has already been said that no lamp can be said to be *of* or to *have* a greater or

* Abstract from a book to be published shortly by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

Digitized by Google

less efficiency than another. One lamp may be run at a greater efficiency than another, and may then be said to be *at* a greater efficiency, but it possesses in itself no greater efficiency, as the other lamp can be equally well run at the higher efficiency.

The higher state of efficiency simply means that the filament is at a higher temperature. Any lamp may be run at any efficiency or temperature up to its breaking point. With incandescent carbon a certain temperature means a certain colour of light and a definite efficiency, either in watts per candle-power or in proportion of luminous radiation to total radiation. Whether the same thing can be said of all incandescent substances does not yet appear to be definitely settled. Certain of the metallic oxides may, perhaps, prove exceptions. The well-known Welsbach gas burner seems to suggest such an exception, but the author does not know of any tests upon this point. Certainly, to the unaided eye, the colour of the light of a Welsbach mantle is absolutely different from that of a gas flame, though the temperature of the particles of carbon in a gas flame might be supposed to be much the same as that of the Welsbach mantle. Certainly neither can be hotter than the gas flame. Possibly, however, the particles of carbon are very far below the temperature of the flame. These particles of carbon certainly have a very great emissivity, and they may, perhaps, radiate heat and light so fast that they never approach the actual temperature produced by the combustion of the gas. On the other hand, the Welsbach mantle, having a vastly inferior emissivity, is raised nearly to the actual temperature of the flame. The emissivity of the Welsbach mantle is extremely low. One which the author measured gave less than eight candles per square inch of surface when new. The carbon in a gas flame gives many times this amount of light per square inch. Accurate tests with a spectro-photometer might settle this question. If the material of the Welsbach mantle is only at the same temperature as the carbon particles in a gas flame, then it must have the property of selective radiation, and may, therefore, be found to have a greater light-giving efficiency than carbon.

In the case of using such oxides as the light-giving portion in electric lamps, one thing is apparent: it is that the extent of radiating surface will have to be very much greater than that of a carbon filament for the same amount of light if at the same temperature.

The only way to ascertain the relative superiority of different incandescent lamps is to run them all at a constant voltage and all at the same efficiency at the start. They must then be tested at periods of, say, fifty hours at the same voltage as the original test, in order to find the diminution in candle-power. Such tests might be called "deterioration" tests. Thus, a lamp which loses 10 per cent. in candle-power in 400 hours is a better lamp than one which loses that amount in 300 hours.

Life tests, pure and simple, are worthless. A great many carefully-ascertained life tests of different lamps have at various times been reported. Such tests are, however, of no value unless the actual tests of candle-power of the lamps at different periods of its life are also given. It is also equally necessary to know within what limits the difference of potential was maintained throughout the run.

All lamps fall off in candle-power when supplied with a constant number of watts. Lamps usually fall off in candle-power from the commencement of their active life, when supplied with current at a constant voltage. The deterioration in this case is, however, sometimes masked during the first hundred hours or so, by the resistance of the filament falling. A greater amount of power is therefore supplied to the lamp, which may, in consequence, give even more light after a hundred hours than it did at the first. Such behaviour is, however, the exception rather than the rule, and seldom occurs in flashed lamps.

What amount of deterioration should be allowed before a lamp is cast aside it is difficult to say. It depends upon the circumstances of each individual case. As long as a lamp gives sufficient light in its particular situation there is no need to change it. A new lamp may be fixed over a writing table, and after a hundred hours may be found to be no longer bright enough, it is therefore taken down, but it will do perfectly well in some other situation, say in a bedroom or passage for a further and longer period. The price of the lamp determines as much as anything the period at which it is thrown away. The cost of a candle-power hour for the actual amount of light given increases as the light of the lamp diminishes. In order that the total cost of maintaining a given amount of light may be a minimum, it is necessary to renew the lamps at certain definite times. The length of time each lamp is used depends in such case upon the price of the lamp, the price of the power, and the rate of deterioration of the lamp. As the last of these conditions is variable even with lamps of the same make, it is impossible to fix the period under any conditions of price of lamps and power. Lamps in ordinary use cannot be tested every fifty hours, and it therefore happens that they remain in use as long as they give light enough.

The length of time taken by lamps of the same make to deteriorate in candle-power by a certain percentage depends very much on their treatment. If the pressure is maintained constant, say within 2 per cent. on either side of the normal, the useful life will be longer than if the pressure is allowed to vary much. The pressure at which electricity is supplied by central stations is anything but constant. The very best supplies are not to be relied upon to keep within 5 per cent. on either side of the normal, while some extensive supply systems do not keep within 10 per cent. The alternating systems seem to be more difficult to regulate than the direct-current ones. Deterioration tests of lamps of the same make on the different supply systems would be very interesting and instructive, and would go far towards settling the dispute as to the relative merits of the various systems in use.

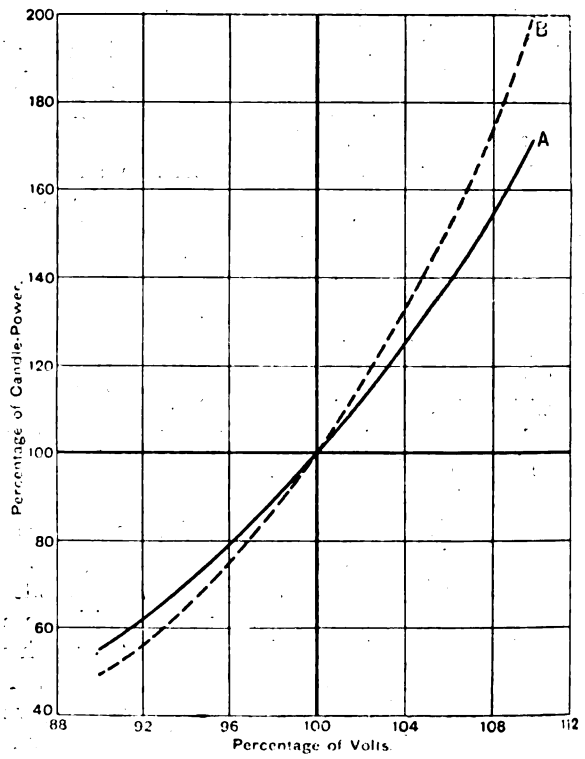

FIG. 40.

In order to show the importance of the constancy of the pressure, Fig. 40 is given. It shows approximately the percentage variation in candle-power for any given percentage variation in the volts over a range of 10 per cent. above and below the normal. It will be found to be about correct whatever be the temperature or efficiency of the lamp at normal voltage. The curve A gives the results when the filament is constant in resistance over the range of 10 per cent in volts. The dotted curve B gives the result if the filament uniformly falls off in resistance by 5 per cent. for an increase of 10 per cent. in the volts. As a rule the values lie nearer B than A. It will be seen that a slight increase in the pressure causes

Digitized by Google

the candle-power to rise greatly, while a slight decrease means a poor light.

The falling off in the candle-power of lamps is due to particles of carbon being thrown off the filaments. This action reduces the light of the lamp in three ways. Firstly, the particles of carbon form a coating on the glass of the lamp, and, therefore, obscure the light given by the filament. Secondly, the nature of the surface of the filament is altered, and its emissivity is increased so that it is at a lower temperature. Thirdly, the resistance of the filament is increased, so that it takes less current, and is again on this account at a still lower temperature. Thus, not only does the filament give less light, but a great proportion of what it does give is prevented from getting outside the bulb. In order to find out what proportion of the total loss of candle-power might be due to these different causes the author made the following somewhat extreme test.

A lamp was tested at about 2 watts per candle-power. It took 51·7 volts and gave 55 candle-power for a consumption of 107·7 watts. It was then run at that voltage until it was much blackened. It was then tested again. At 51·7 volts it gave only 12 candles, and, owing to rise in resistance, it took only 100 watts. The total loss of candle-power was therefore $55 - 12 = 43$, or 78 per cent. In order to find out how this loss was made up, the filament was taken out of the blackened bulb and put into a new one. The air was then exhausted to the same degree as before, showing a very good vacuum by the spark test. The lamp was then again tested. At 51·7 volts it took 100 watts, and gave 30 candles. It was then run a little brighter so as to take the original power of 107·7 watts, and it gave 42 candles and took 52·8 volts. The loss of light due to the blackened bulb was therefore $30 - 12 = 18$ candles $= 60$ per cent.

The loss due to increase in emissivity is given by the decrease in candle-power, when the same amount of power was supplied to the filament. The loss due to change in emissivity is therefore $55 - 42 = 13$ candles $= 23{\cdot}6$ per cent.

The loss due to change in resistance is given by the difference in candle-power when the filament was supplied with the original number of watts, and when supplied with the original number of volts; because, had the resistance not gone up, the original number of volts would have given also the original number of watts. The loss due to increased resistance is therefore $42 - 30 = 12$ candles in $55 = 21{\cdot}8$ per cent. The rise in resistance is about 8 per cent. The loss due to change in emissivity plus that due to change in resistance, therefore $= 13 + 12 = 25$ candles $= 45{\cdot}5$ per cent.

This result is also shown by the difference between the original candle-power and that at the original volts when the filament is in the new bulb, *i.e.*, $55 - 30 = 25$ candles. It is therefore apparent that the filament at the original volts gives 25 c.p. less than it gave at first. It gives only 30 candles, or 54·5 per cent. of its original candle-power.

We have already seen that the blackened glass obstructs 60 per cent. of the light of the filament; therefore, of this 54·5 per cent. of light given by the filament, 60 per cent. is stopped by the blackened bulb.

60 per cent. of 54·5 per cent. $= 32{\cdot}6$ per cent. The total reduction in the light of the lamp is therefore made up in the following way:—

Less light given by filament, owing to	Candles.	Per cent.
(1) Increase in emissivity	13	23·6
(2) ,, resistance	12	21·8
Total (1) and (2)	25	45·4
(3) Stopped by blackened glass	18	32·6
Total reduction	43	78·0

The greater part of the decrease in the light of the lamp is therefore, due to the fact that the filament gives less light. Of the light which it does give only a part gets through the blackened bulb.

Though the above test may be considered an extreme one, the lamp having been very much overrun, the same kind of result undoubtedly occurs in lamps run at ordinary temperatures.

The black deposit on the bulb of a lamp stops not only much of the light radiation, but also much of the heat. The result is that a blackened lamp gets hot. A much blackened lamp may often be found to be too hot to hold.

The effect of a fall in the resistance of a lamp is strikingly shown in the following test: An unflashed lamp had just been tested at 50 volts. It gave 12·5 candles, and took 0·82 ampere, and, therefore, 41 watts, and its resistance was 61 ohms. It was then accidentally run for an instant at 100 volts. The testing was being done on a 100-volt circuit, and the resistance in series with the lamp was momentarily short-circuited. The bulb was in consequence blackened, and the filament had lost its shiny appearance. It was therefore expected that a great diminution in candle-power would be observed at 50 volts. The resistance of the filament had, however, been so much reduced as to more than counteract the dulling effects. The lamp tested 50 volts, 1·03 ampere, 22 c.p., and, therefore, 51·5 watts and 48·5 ohms. The resistance had gone down 20 per cent., so that the lamp took so much more power than it did at the first that the increase in emissivity which undoubtedly occurred was not sufficient to prevent a great increase in the temperature of the filament; and the blackening of the bulb, though great, was also not sufficient to mask the effect of the great increase in the light given by the filament.

If a filament could be found whose resistance gradually fell as its emissivity increased and the bulb blackened, a lamp of uniform candle-power or of uniform watts per candle-power throughout its life might be possible. Such a lamp would not have so long a life as one of which the resistance increases, but it would have a more useful life, and would automatically end its career at the proper time. Unfortunately, the filaments which are usually found to fall in resistance do so during the first part of their life, when they should remain constant, and when they should be going down they increase.

(To be concluded.)

A POTENTIOMETER METHOD OF MEASURING THE ELECTROMOTIVE FORCE OF TRANSFORMERS.

BY BERNARD P. SCATTERGOOD.

Engineers who have had experience in making workshop tests of dynamos and transformers will know what difficulty there is in arriving at results which can lay claim to any degree of accuracy, when the engine which is the only available source of power has to drive a number of heavy machines in addition to the dynamo. Under such conditions it is impossible to secure anything like a constant dynamo speed; and with a primary voltage varying between perhaps 1,900 and 2,100 volts, or within even wider limits, it is not easy, to say the least of it, to read the secondary voltage of a transformer to within even 2 or 3 per cent. It was to overcome this difficulty that I originally designed the method to be shortly described, in the development of which some interesting results were arrived at. From certain analogies with Poggendorf's well-known test, I have called it a "potentiometer" method.

The method I adopted was to couple the secondary of the transformer whose open circuit E.M.F. was to be measured, in series with that of a standard transformer of which the secondary E.M.F. at the normal primary voltage (in this case 2,000) was accurately known. The primaries of the two transformers were connected in parallel on the high-tension mains, in such a way that their secondary electromotive forces were opposed; and in the secondary circuit was placed the thick coil of an auxiliary step-up transformer of known conversion ratio, across the fine wire coil of which was connected a Kelvin multicellular electrostatic voltmeter. The arrangement is shown in Fig. 1. Under these circumstances, the standard transformer and that

Digitized by Google

under test both being unloaded, their secondary electromotive forces are in opposite phase to those in the respective primaries; and as the method of coupling up ensures that the primary voltages at the terminals of the two transformers are in opposite phase to each other, this is also the case with the secondaries. Hence, if the two secondary electromotive forces are exactly equal, they balance each other; no current flows in the circuit, and no deflection is seen on the voltmeter. But supposing them to be unequal, then there is a resultant E.M.F. in the circuit, namely, the difference between the two secondary electromotive forces; this being impressed as a potential difference at the terminals of the step-up transformer, is magnified by the fine wire coil in the ratio of the windings, and the deflection of the voltmeter needle thus becomes a measure of the difference between the E.M.F. of the standard and that of the transformer which is being tested. As the former is known the latter is thus at once arrived at.

The subject of the first experiments which I made to test the feasibility of the method was a 2-H.P. Lowrie-Hall transformer (No. 1,669), of which the secondary E.M.F., with 2,000 volts on the primary, had been carefully determined by several direct measurements, and found to be 102·15 volts. The secondary E.M.F. of the transformer used as the standard was, as nearly as could be measured, 100 volts; it was wound with 100 turns on the secondary, thus giving one volt per turn. In addition to the ordinary secondary winding, it had 10 extra turns wound upon it, in four sections of one, two, three, and four turns respectively, all or any of which could be connected in series with the main secondary coils, and in such a way as either to help or to oppose the latter. Thus the voltage at the terminals of the standard could be varied at will from 90 up to 110. The necessity for being able to adjust the standard voltage in this way will be clear from the consideration, that from a single voltmeter reading it is impossible to say whether

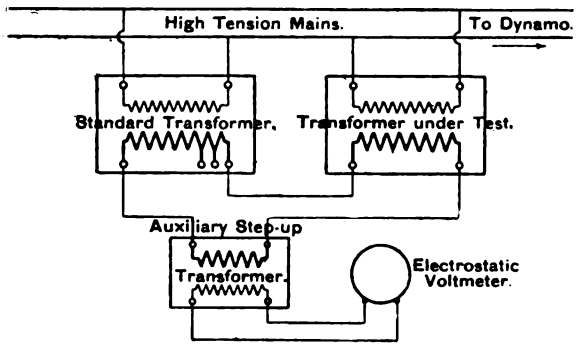

FIG. 1.

the actual E.M.F. of any transformer is greater or less than that of the standard. Thus, two transformers having open circuit electromotive forces of 103·28 and 96·72 volts respectively would each of them give the same resultant E.M.F of 3·28 volts, if that of the standard were 100; and the voltmeter deflection would be the same in the two cases. A second reading, however, with a different voltage on the standard, at once settles the matter. For example, the standard E.M.F. is raised, say, to 100 volts; then, if the deflection is increased, obviously the E.M.F. which is being measured must be less than 100; if the deflection is diminished, the E.M.F. must be greater than 100. The best way to make the adjustment of the standard voltage is by means of plugs similar to those of a P.O. box, by which a greater or lesser number of turns of secondary are put in circuit. The details of such an arrangement will readily suggest themselves; but, of course, it must not be done by short-circuiting the coils.

The auxiliary transformer used in the preliminary experiment was a 2-H.P. transformer of conversion ratio 1 to 20, and similar to that which was used as the subject of the test. The frequency of the alternations was about 120.

With the connections arranged as in Fig. 1 a series of readings was taken with different voltages on the standard, throughout the range of its adjustment. In the second column of Table I. will be found the observed voltmeter deflections; these are, as will be seen, very nearly proportional to the standard voltages at which they respectively occur. But before describing these results it will, perhaps, be better to briefly indicate those which theoretical considerations might lead us to expect.

If a series of readings, such as that above referred to, were to be plotted on squared paper, with standard voltages as abscissæ, and the corresponding voltmeter readings as ordinates, it will be seen that theoretically the curve should consist of two straight lines, equally inclined to the horizontal axis, and meeting at a point within it; and, further, that the shape of the V which forms the curve depends on the conversion ratio of the auxiliary transformer used, the tangent of the angle of inclination of the lines to the vertical axis being, in fact, numerically equal to this ratio, provided that the vertical and horizontal distances are plotted to the same scale. Evidently, too, the point on the horizontal axis on which the apex of the V rests is the point where the two electromotive forces, that of the standard and that of the transformer under test, balance

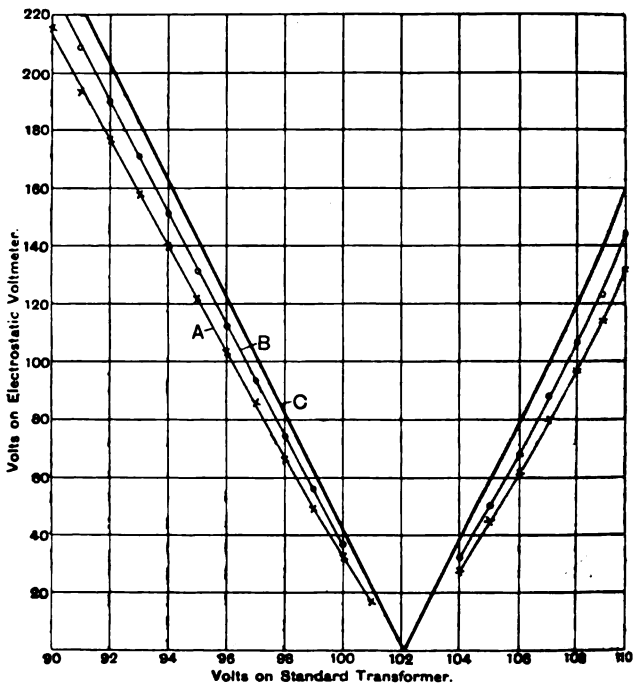

FIG. 2.—E.M.F. Curves (at No Load) of a 2-H.P. Lowrie-Hall Transformer (No. 1,669).

A, Auxiliary Four 2-H.P. Transformers in Parallel; B, Auxiliary Two 2-H.P. Transformers in Parallel; C, Theoretical Curve.

each other, and the E.M.F. of the latter can, therefore, be at once read off, being equal to the standard voltage at this point.

Now, if our observed readings are plotted in the manner indicated above, it will be seen that the sides of the V which form the curve are not quite so steep as they should theoretically be; in other words, the voltmeter deflections corresponding to the several standard voltages are all of them slightly less than they ought to be. This may be expressed by saying that the "virtual conversion ratio" of the auxiliary has a greater value than that indicated by the ratio of the windings. The sides of the V, too, are not perfectly straight lines, but bend slightly inwards towards each other near the bottom of the curve. This effect, though not very marked in the particular instance taken, becomes in some cases very noticeable.

So much for the discrepancies between theory and observation, with the causes of which I hope to deal more fully in a future Paper. At present it is sufficient to say that they arise from a drop in voltage, partly due to resistance in the circuit external to the auxiliary (I R drop), but chiefly to magnetic leakage. I shall show, however, that these disturbing elements can be entirely eliminated in practice. The important thing to be noticed just now is that the vertical axis of the V curve, plotted from the observed readings, cuts the horizontal line of standard voltages at what is known to be the voltage of the transformer, namely, 102·15 volts.

Digitized by Google

It is obvious that any method of testing which necessitated 20 separate readings and the drawing of a curve in order to determine the secondary E.M.F. of a transformer would not be a practical one. Fortunately, however, this is not the case; but the practical application of the method to workshop testing I shall defer until I have described the experiment made in order to determine the influence which the nature of the auxiliary transformer used has upon the results obtained. For this purpose I arranged three additional 2 H.P. transformers, similar in all respects to the one previously used as the auxiliary, of which the secondary (thick) coils could be connected in parallel. The conversion ratio of each transformer was 1 to 20. Thus by using one pair of primary terminals only, or two, three, or four in series, the potential difference at the secondary terminals could be multiplied 20, 40, 60 or 80 times, as might be necessary. Four sets of readings were taken, the first (that which has been referred to above) with only one transformer as auxiliary; the others with respectively 2, 3, and 4 transformers with their secondaries in parallel. The results obtained are tabulated below, and two of the sets of readings are reproduced graphically in Fig. 2, in which the curves marked *a* and *b* correspond with the readings taken with four and with two auxiliary transformers respectively.

Table I.—*Showing observed Voltmeter Deflections at Different Standard Voltages, with one, two, three, and four Auxiliary Transformers (No. 1,669, no Load).*

Voltage of standard.	Voltmeter deflections.			
	Auxiliary, one transformer.	Auxiliary, two transformers. (Fig. 2, B.)	Auxiliary, three transformers.	Auxiliary, four transformers. (Fig. 2, A.)

109	130	123	118½	114
110	150	143	138½	131

For the sake of clearness in the diagram the curves for one and three auxiliary transformers are not shown; but it will be seen from the table that, for the same standard voltage, the voltmeter deflections obtained with four, three, two and one transformer are practically in arithmetical progression. It is accordingly allowable to extend the series a step further, and by extrapolation to obtain a fifth set of figures which corresponds, so to say, to *no* auxiliary transformers; that is, to an auxiliary transformer of infinite impedance, representing the case where the whole E.M.F. in the circuit is impressed at the terminals of the auxiliary. This has been done, and the result is the curve marked C in the diagram ("theoretical curve"). It will be seen that this is actually the curve which we should expect to get after eliminating the disturbing causes alluded to above; the slope of the lines being such that the tangent of the angle of their inclination to the vertical axis is exactly equal to the conversion ratio (1 to 20) of the auxiliary transformer used; or rather, it would be equal to this ratio if horizontal and vertical distances were plotted to equal scales. In the actual diagrams, as will be seen, the vertical distances are to a scale ten times smaller than the horizontal.

Now let the deflections which constitute the right-hand branch of the curve be considered as negative, and plotted therefore below the horizontal line of zero deflection; the V-shaped curves of Fig. 2 then assume the form of nearly straight lines, as in Fig. 3, all of which cut the horizontal axis in one point, the balancing point. Hence it is plain that all disturbing effects are eliminated by simply taking two readings of the voltmeter on opposite sides of the balancing point, preferably adjusting the standard voltages so that these deflections are as

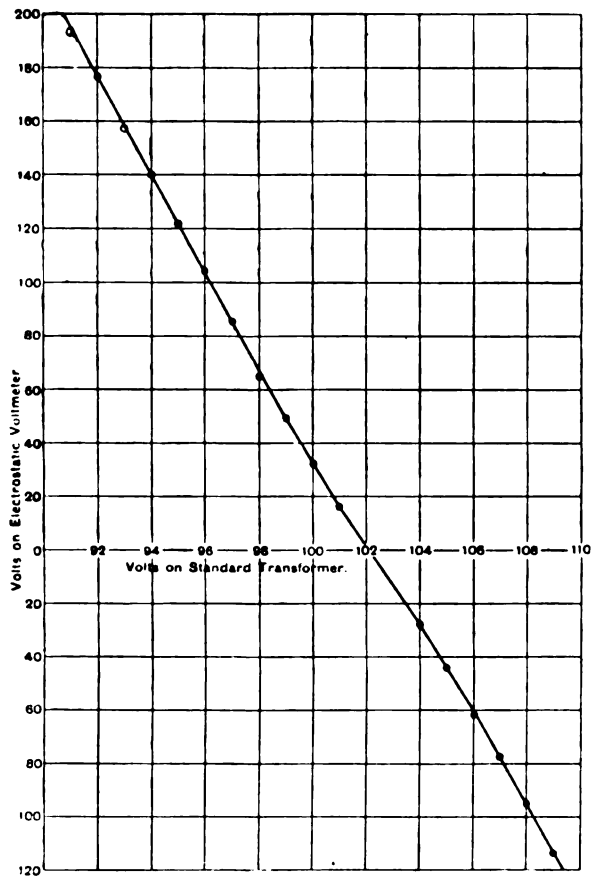

FIG. 3.

nearly as possible equal. The reason for this lies in the tendency above referred to, of the lines to become slightly convex to the horizontal axis as they approach it. By taking two nearly equal deflections on opposite sides of zero the effect of this deviation from straightness is eliminated.

(To be concluded.)

NOTES ON THE E.M.F. & TEMPERATURE COEFFICIENT OF THE CADMIUM MERCURY CELL.

BY ARTHUR DEARLOVE.

A type of this cell is patented by Mr. Weston, and it is suggested by him that it should be accepted as a standard of E.M.F. The cell, its form, and the method to be followed when setting it up, is described by him in his Patent No. 22,482, dated 1891. (Mr. Weston states in his patent that the E.M.F. of this combination is 1·019 true volts, and that its temperature coefficient is 0·01 per cent. per degree Centigrade.)

Briefly stated, the cell consists of electrodes of pure mercury and cadmium amalgam, with a saturated solution of cadmium sulphate and protosulphate of mercury. I mention here the fact that the latter salt should be in excess. Unless this is so I found the E.M.F. to be somewhat higher than that given below.

From the above remarks it will be seen that this cell differs from "Clark's standard cell" in that cadmium amalgam and cadmium sulphate solution is used in place of the pure zinc and zinc sulphate solution employed in Clark's standard of E.M.F.

Digitized by Google

The following notes are merely a record of my endeavours to construct these cells satisfactorily, and to investigate their claim to be regarded as standards of E.M.F.

This experience may be of some value to those who, like myself, wish to set up the cells and have nothing to guide them but the instructions given in Mr. Weston's patent.

The first cells made were set up in June, 1892; the amalgam used was prepared by heating mercury and cadmium together in a crucible, adding cadmium, until specimens of the amalgam on cooling were found to be sufficiently rigid to retain the form of a rod. The exact proportion of the metals was not in this instance determined, but was approximately 5 parts of mercury to 1 part cadmium by weight.

The solution was prepared carefully, using distilled water and pure sulphate of cadmium. The saturated solution of Cd Sulph, when setting up the cells, was heated with the washed protosulphate of mercury, as is usually done with the zinc sulphate and protosulphate of Hg when making the Clark cell.

The complete cell is shown in Fig. 1.

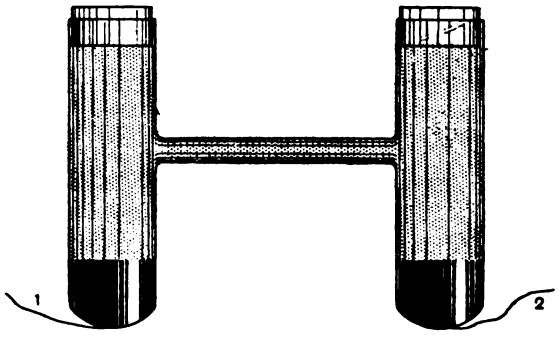

FIG. 1.—Cell containing Mercury in contact with Wire No. 1 and Cadmium Amalgam in contact with Wire No. 1. The rest of the cell is filled with a saturated solution of Cadmium Sulphate and Protosulphate of Mercury.

The following figures show the results obtained, the E.M.F. in T.V., and the temperature coefficient of the cells between the limits given :—

No. of cell.	June 1st, set up.	June 10th.	June 13th.	June 16th.
1	1·0398	1·034	1·0351	1·0354
2	1·0386	1·034	1·0348	1·0340
3	1·0373	1·036	1·0370	1·0365

The above figures are corrected for temperature by the values given below.

The temperature coefficient per degree Centigrade of these cells was found to be respectively as follows :—

Cell.	Between 0°C. and 15°C.	Between 15°C. and 27°C.	Between 27°C. and 43°C.
1	0·024 per cent.	0·05 per cent.	0·037 per cent.
2	0·0235 „	0·046 „	0·030 „
3	0·0205 „	No. 3 broken.	.....

Clark's standard cell and slides method was used for purposes of determination.

These figures showed no remarkable agreement, either as regards E.M.F. or temperature coefficient, with the values given by Mr. Weston, and some experiments were made with amalgams of different proportions of cadmium and mercury. The ratio of these two metals appears to have an important bearing on the resulting E.M.F. of the cell; this is clearly shown to be the case by the figures given in the subjoined table, where the E.M.F. of variable proportions of cadmium and mercury are given :—

	E.M.F. True Volts.
No. 1 cell. Cad-Amal, with large proportion of Hg	1·0377
„ 2 „ „ smaller „	1·0550
„ 3 cell, with pure cadmium amalgamated	1·0436
„ 4 „ „ electrode	1·0800

Another cell of H form was set up with 36 grammes of pure mercury in each leg and a saturated solution of Cd Sulph and Protosulph. Hg to one side of the cell, finely divided cadmium in definite proportions was then gradually added, the E.M.F. being taken after each addition of cadmium :—

	E.M.F. in T.V.	Remarks.
1st—Pure Hg V. Pure Hg.....	Nil	—
„ V. 1 Parts. Cd & 100 Parts. Hg..	1·00	Unsteady when shaken
„ 2 „ „ „	1·0065	„ „
„ 5 „ „ „	1·0139	„ „
„ 7 „ „ „	1·0164	„ „
„ 10 „ „ „	1·0168	Only slightly.
„ 14 „ „ „	1·0192	Steady when agitated.

It is evident from the above figures that the E.M.F. is a variable quantity dependent upon the amounts of cadmium and mercury with which the amalgam is formed.

Until the proportion of cadmium equals at least one-seventh by weight of the mercury, neither the E.M.F. or the temperature coefficient are near the values given by Mr. Weston.

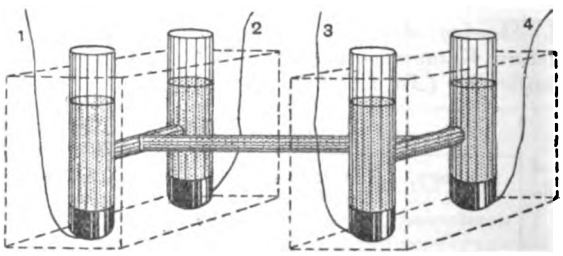

FIG. 2.—Cells containing Mercury in contact with Wires Nos. 1 and 3, and Cadmium Amalgam in contact with Nos. 2 and 4. The rest of the cell is filled with a saturated solution of Cadmium Sulphate and Protosulphate of Mercury. The dotted lines represent the outer vessel.

I noted also as a peculiarity of this cell that until the proportion of 7 Hg to 1 Cd is reached, that agitation or disturbance produced violent changes in the E.M.F. When this proportion is arrived at the cell remains practically steady and constant in E.M.F., though subjected to treatment which Clark's standard cell would not allow of without misbehaviour.

Having practically decided this point three other cells were made, one of the ordinary H form, and the others may be described as a double H cell. Each cell was enclosed in a separate vessel, the arrangement is represented by the Fig. No. 2. This mode of construction allowed of one cell being kept a constant temperature, whilst the temperature of the other was varied at will.

Four combinations were possible with this form, and I was able to determine which electrode was affected by change of temperature and caused the increase or decrease of E.M.F. The table following gives the results of tests made from time to time over a period of nearly a year :—

Value in True Volts uncorrected for Temperature Variations.

Cell.	June 25, 1892.	June 27, 1892.	July 26, 1892.	Oct. 13, 1892.	Apr. 28, 1893.	May 15, 1893.	May 30, 1893.
A } double H {	1·029	1·030	1·030	1·028	1·032	1·032	1·030
B } double H {	1·027	1·028	1·030	1·030	1·029	1·029	1·030
C	1·026	1·029	1·032	1·031	1·029	1·029	1·030
Temp. at time of obs.	17·5°C.	19·5°	18·5°	15·0°	15·6°	17·0°C.	15·7°C.

The behaviour of these cells has not been entirely satisfactory, but the results are not discouraging to the idea that a cell of this pattern can be made having an E.M.F. of a constant value, and, what is of considerable importance, a variation of E.M.F. on change of temperature, which between the limits of 0° and 20°C. is certainly not higher than 0·01 per cent. per degree, and may be as low as 0·003 per cent. per degree C.

The reason why the E.M.F. of these cells is higher than the 1·019 mentioned is that the amalgam was not of the 7 to 1 proportion; 10·8 grammes of cadmium were used with 58·3

Digitized by Google

grammes of mercury; the temperature coefficient between 15° and 43°C. was 0·016 per cent. per degree.

It was found that practically the whole change of E.M.F. occurring on decrease or increase of temperature was due to the effect of such changes on the amalgam. The highest E.M.F. obtained was with cadmium amalgam at 0°C. and mercury at 19°C.; the lowest was noted with cadmium at 19° and mercury at 0°C.; in other words, the *lower* the temperature of the amalgam electrode the *higher* the E.M.F., and to a smaller extent the *higher* the temperature of the mercury the *higher* the E.M.F.

The work was now interrupted, but in May this year a number of cells were set up, the actual weights of Cd and Hg in the amalgam being 42½ and 281 grammes respectively, or a 1 to 7 proportion.

As before, Clark's standard cell and the slide method was used in all cases, the Clark cell being corrected for temperature variations.

The E.M.F. is given for these cells at the temperatures 15·5deg., 33·5deg., and 64deg.

No. of cell.	True volts 15·5 C.	33·5°C.	64°C.	Per deg. C. Temp. coeff. between 15·5°C.	
				33·5°.	64
1	1·0197	1·0185	1·0159	0·007%	0·008%
2	1·0196	1·0185	1·0146	0·006%	0·010%
3	1·0194	1·0189	1·0143	0·003%	0·010%
4	1·0189	1·0184	1·0142	0·003%	0·010%
5	1·0193	1·0186	1·0161	0·004%	0·007%

The temperature coefficients given are roughly calculated, and no explanation can be offered as to the difference in its value for the various cells, as they were all taken under exactly the same conditions and at the same time.

As these cells fell to normal temperature from 64°C., their E.M.F. was taken at three temperatures, viz., 40°C., 24°C. and 17°C. the thermometer was inserted into the cell itself and showed the temperature had fallen to these values, the E.M.F.'s, however, showed no appreciable change for some considerable time, and then exhibited comparatively a large amount of irregularity between themselves.

After subjecting these cells to these tests, they never quite regained their original value at the normal temperature, the E.M.F. remaining lower to an appreciable extent.

I regret that the following determination was not made before the one remarked upon above, as I consider the results may have been affected by their previous treatment.

The values obtained for the E.M.F. at 15·7deg. and at 0°C., with the tests showing their subsequent recovery, are tabulated below:—

No. of cell.	Temperature 15·7°.	At 0°C. after three hours' immersion in crushed ice.	Three days after this experiment.
1	1·0176	1·0178	1·0189
2	1·0178	1·0165	1·0184
3	1·0172	1·0160	1·0180
4	1·0167	1·0170	1·0178
5	1·0167	1·0167	1·0178

It will be seen that the temperature coefficient between 15·7°C. and 0°C. is very small and somewhat irregular; but for almost all practical measurements, the temperature correction may be neglected.

It was noted that the alteration of E.M.F. follows the change of temperature very slowly, and under the same conditions Clark's standard cell behaves in a similar way.

The above five cells have been tested from time to time since construction, and have satisfactorily maintained their original values.

Attempts to form these cells electrolytically, using a current of 0·25 and 0·5 amperes, were not successful. The salt of mercury thrown down by this process was yellow, and is known as "turpeth mineral." Their E.M.F. was higher than that when pure photosulphate is present.

Some cells have been set up by Dr. Muirhead under the conditions mentioned by myself. He has forwarded to me the following results, which may be considered entirely satisfactory.

The first six cells are made with 7 parts Hg to 1 cadmium by weight, and No. VII. has 6 parts Hg to 1 cadmium. The Board of Trade value of 1·4345 volts at 15°C. is taken for Clark's standard cell used.

No. of cell.	July 9, 1893.	July 12, 1893.	——
1	1·0190	1·0190	7 parts Hg to 1 Cd
2	1·0193	1·0190	" "
3	1·0190	1·0189	" "
4	1·0190	1·0189	" "
5	1·0189	1·0189	" "
6	1·0188	1·0188	" "
VII.	1·0196	1·0196	6 parts Hg to 1 Cd

The temporary coefficient of the above cells between 2·5°C. and 22°C. was found to be 0·008 per cent.

On September 20th last I witnessed the tests for E.M.F. of this batch of cells, and found that they had maintained with exactness the values given for the tests made on July 12, 1893.

General Conclusions.

1st. That a more lengthened experience with the Weston cell is necessary before speaking of it as a possible rival to Clark's standard of E.M.F., whose constancy under proper treatment is maintained for years.

2nd. The cell is set up with ease, and considerable accuracy is attained. One may say that proof is given in these notes that separate workers using different materials arrive at practically indentical results.

3rd. The cell submits to rough treatment and maintains its E.M.F. constant.

4th. That the low and almost negligible temperature coefficient of the cell, not amounting to $\frac{1}{10}$th that of the Clark cell, is an undoubted and important advantage.

The cell set up in the H form, as suggested by Mr. Weston, has the disadvantage of not being *portable*. Dr. Muirhead and myself have designed a cell which overcomes this difficulty.

The modifications we have introduced and adopted impair in no way the constancy or merits of the cell as regards its electrical behaviour.

In this *portable* type of a cadmium-mercury cell, as constructed by Dr. Muirhead, the cadmium amalgam electrode is either cast round a platinum spiral or pressed down tightly into a perforated glass tube; the free mercury electrode is replaced by an *amalgamated* and closely wound platinum spiral. The complete cell is then fitted in an outer case similar to that provided with the Clark's standard.

PRACTICAL MACHINE-SHOP INSTRUCTION IN TECHNICAL SCHOOLS.*

BY PROF. JOSEPH TORREY.

In any discussion of technical-school instruction it must be treated as an existing, and not an imminent, thing. It is out of the pioneer stage, and more or less independent of criticism. In fact, barring seniority, which is not a very lucrative possession, the technical schools have, all round, rather the best of the colleges. Anyone who studies their history in this country will be greatly impressed with the high ideals and broad wisdom of the men who were instrumental in evolving them, and yet, if he has been a careful student of human history, he will say to himself that institutions have not always been able to carry out the purposes of their founders, and he will naturally inquire how far the ideals of the founders are being realised in the modern technical schools.

In most modern systems of technical education the machine-shop holds a prominent place. What is its object? Is it intended to furnish a species of apprenticeship from which boys shall emerge machinists, or is it simply a laboratory, and amenable to the same limitations and laws as any other educational instrument?

At the very outset we shall find that the answers to the foregoing questions depend largely on what answers we give to another

* From the *Engineering Magazine*, October, 1893. (London: 1, 2 and 3, Salisbury-court, Fleet-street, E.C.)

Digitized by Google

similar set, involving the aims and objects of those who attend these schools, and the results of the training they gain there as shown by their after experience. These questions we can answer in a general way quite readily. The greater part of those who enter the technical schools are comparatively young students with often only a scanty equipment of fundamental knowledge. They enter on a technical course of training with a view to utilising that training afterwards as a means of livelihood. Very few of them mean to be machinists, moulders, engineers, carpenters, or mechanics of any kind. Many of them aspire to positions of responsibility and trust in manufacturing establishments, and by coming to the technical schools instead of serving an apprenticeship in the works they virtually pronounce it their opinion that, all things considered, this is the better and surer course to take.

If this is a fair statement of the case—and I think it will be generally accepted as such—we should expect to find the technical schools planning their work and adjusting their equipment to meet the requirements of such a class of students as has been sketched. Educational institutions are moulded not by trustees or founders in most cases, but by students. If, then, we enter upon any discussion of the methods and appliances of the school shops, it is clear that we must consider them from this point of view—not as training schools for mechanics, but as having in view the development of men more particularly fitted to deal with wholes rather than with their parts. The question is, then, Are the methods and appliances of the school shop adequate to the task of producing men capable of taking important positions without considerable supplementary experience in the works? First of all we must inquire, What are the qualities which such a position demands in him who holds it?

To begin, he must have a certain just and well-earned independence—or, better, freedom—of thought and judgment. In the second place, he must be far-sighted, able to see over the heads of his men, planning far in advance such changes as will be necessary to meet the demands of the times, always watching tendencies and not the mere order of events. He need not be an especially skilful mechanic himself, but if he can add this to the foregoing qualities it will certainly increase his efficiency. Finally, he must command the respect and regard of those under him, and have the power to make them enter into his ideas and work out his plans. Such, broadly speaking, are the qualities which must characterise a man who holds any responsible position in a manufacturing establishment. Now let us analyse these requirements, see how they may be attained, and judge, as well as we can, whether the technical school shops are likely to furnish the requisite conditions.

Independence of thought and judgment usually comes from two things—experience and much thinking. Neither one alone can bring it about. The same is true, only perhaps in a higher degree, of far-sightedness. The other essential qualities mentioned are, I think it will be conceded, largely matters of temperament and disposition.

How much, now, can the technical school do toward equipping a man with such qualities? Can it, in the first place, give experience? If so, to what extent? This question has been discussed over and over again. The very best engineers in America have devoted special sessions of their meetings to it, but I cannot find that it has been seriously maintained that the amount of work done by a student in the shops of a technical school can be taken as so much practical experience. The time is too short, the view too limited, and, moreover, there is lacking in most cases the reality of actual shop-work. The most serious obstacle, indeed, to the successful employment of the school shop as a means of actual practical experience is found not in the shop itself, though it has its limitations here, but in the student and in the atmosphere of student life. We may talk, if we please, about the earnestness of students, and may fancy, if we see fit, that we find more of this desirable element in the technical school than in the college, but as a matter of fact every year sees less and less difference between the institutions in this respect. In both of them conditions have changed considerably within the last ten years. The life of the student is more complex now than it formerly was, and the element of *study* is only one among a number, all of which demand some attention. As a whole the change has probably been a beneficial one, but we certainly have been obliged to forfeit something. Then, again, the very largely increased number of students, which is such a perplexing element in the educational problem to-day, has tended, as it must necessarily do, to make classes more unwieldy and work of all kinds more mechanical. Nor can it be truly said that the laboratory and laboratory instruction have escaped this. Every one who is connected with such instruction knows that most students regard the work simply as a set of things to be done, and in the doing of which they must attain a certain degree of accuracy. The question that the teacher hears most of in the laboratory, and that depresses him most, is, "Will this do?" or, "Is this good enough?" The mischief is often done, moreover, before the man gets to the college or the technical school. Their influence and traditions reach far back to the boy in the grammar school, and in most cases when he comes to college or to his special school, whatever it be, he is entirely *au fait*, and settles into the harness immediately with a pretty good understanding of what will be required of him, and how he can meet requirements most easily.

To some extent, then, we must take this matter into consideration. A young man working at his bench in the machine-shop of a school is a *student*, and lives the life and thinks the thoughts of a student. Put the same man at work where he can barely earn a living, and where a mistake means so much spoiled material and wasted time, and may cause him to be put back, and he is obliged to labour in a very different way. It is one thing to stand over a steam-engine, take a few cards, adjust a valve, set an eccentric, or scrape a bearing in the engine-room of the technical school, and quite another thing to stand over a fast engine driving machinery which *must not* stop and which has obligingly taken the opportunity to develop a hot crank-pin or a broken piston-ring. The mere agony of soul of such an hour calls out a man's resources as never before.

It is hardly possible to emphasise this point too strongly. The difference is not so much in the things done as in the attitude and standpoint of the man himself. If we undertake to criticise the equipment of the school shop and the plan of work therein carried out as if the fault were to be found there, we shall find our task a very difficult one. The tools and machines are in most cases excellent. If any criticism at all were to be made perhaps the most just one would be that the machines and tools are a little too good. It certainly is a matter of experience that the best kind of apparatus for a beginner to work with is such as makes success depend, in the main, upon his own judgment and skill in handling it. The best training in measurement is afforded by comparatively rough instruments, stress being laid mainly on the point that with instruments of a certain degree of correctness we can reach a result of a certain order of accuracy. By studying carefully the conditions we can perhaps improve our first results a little; but ultimately we reach a well-defined limit which can be passed only by using better instruments. If this step be taken, and the possibilities and limitations of the problem be studied anew in the light of the increased field of errors introduced by changing to more delicate instruments, we can attain to a result which will be of a higher order of accuracy than the first one. I believe this principle could be applied with great advantage in some lines, at least, of shop-work. I have many times noticed in graduates of technical schools a tendency to use instruments in an unintelligent way. For instance, I have seen indicator-cards figured to $\frac{1}{1000}$ of a horse-power when the reducing gear was very loose on centres, and the cylinder had not been measured. I have seen measurements made with a wooden ruler graduated to $\frac{1}{8}$th of an inch recorded to hundredths of an inch. I have seen the weight of cast-iron pieces calculated to the thousandth part of a pound with no real knowledge of conditions which would warrant such exactness of statement. Such performances are not by any means uncommon. One of the rarest sights to be seen in any kind of laboratory, mechanical or otherwise, is a student whose work is *consistent* throughout, and who has the judgment to carry his measurements to a point indicated not by the limit of the graduation on the scale, but by his own clear perception of the conditions, requirements, and possibilities of the case.

I believe that a student will make better progress in this direction with rather rough instruments, but much can be done toward cultivating the corresponding habit of mind, no matter what kind of instruments are employed. So also with machine work. It is not so important that a young man come from his shop training able to make a good fit as it is that he be able to rightly estimate the real accuracy of his work. Let him be taught that he is not to ask his instructor whether the work is "close enough." He is to know for himself just how close it is, and just how well it meets the requirements of the case.

Students differ very widely in this respect. Some need only a hint, and never lose sight of the idea, which fits perfectly into their natural ways of doing things. Others learn only in a sort of automatic way, and never work with any freedom. It is vain to expect anything different. The engineering sense is, to a great extent, born in a man. If it is there, it will permeate any kind of a course of training whether taken at the apprentice's bench or in the shop of the technical school. If it is not there, no amount of training can *create* it. Some men who have had all the advantages of both school and shop experience seem never able to grasp firmly fundamental principles. One designs his first machine without any due appreciation of the fact that strength is good only when it is in the right place—when it is actually opposed as a resistance to deflecting or distorting forces. Another, carried away by his interest in designing a certain piece, or carrying out a certain idea, emasculates his work by too much detail and wastes time and material on something which, when completed, is only a blunder. Or there is a failure, through short-sightedness, to provide for all the requirements. I recently saw a newly-designed tram locomotive in which the generally desirable quality of rigidity had been

Digitized by Google

carried so far that the machine refused to go round a curve. Such mistakes as these do not always come from a lack of what I have called the engineering sense. Quite frequently they simply indicate the lack of a kind of experience which is only obtained by close and living contact with actual conditions as they are found in practice.

It is clear now, I think, that most of the qualities necessary to a man who is to take a responsible part in mechanical matters are such as belong to a somewhat mature mind. In most cases time and experience only will bring such maturity, but certain it is that the school, and particularly the school shop, can bear a very important part, not only by supplying elementary knowledge, but by inducing in the student habits of mind which will follow him into active life. This, it seems to me, is the natural function of the technical school. While a man remains a student he thinks and works as a student. He is impressed mainly with the multitude of facts surrounding him. He deals largely with books and thinks in book form. He has little experience to go on, and so lives largely in the experience of others. All this is well if only his eye penetrates behind the practice and grasps the principle. Sometimes this is the case, but not generally. Whatever else may be said of the atmosphere of the modern technical school, it is not a reflective one.

Just here the influence of the teacher cannot be too strongly emphasised. If he is himself a practical man in the true sense, possessed of a clear head and of creative energy, one who has been accustomed to deal with facts at first hand, he can, if he has the spirit of a true teacher, impart to his students something of his own mental stamp, so that they too will think for themselves, and all their work will show the freshness of *real* originality. It has always seemed to me, moreover, that the students might profitably be thrown on their own resources more than is generally the case. Of course, the chief obstacle to doing this lies in the effort to get a class over a certain amount—generally a considerable amount—of ground in a given time. It is just this effort that should be especially deplored as fatal to the attempt to turn out clear and independent thinkers. It is neither in amount of work done nor in multitude or completeness of appliances, but in the moulding and enlarging influence of an inspiring teacher that the chief possibility of the technical school is to be found.

To sum up: the technical school furnishes, in its machine-shop, a laboratory, not an apprenticeship. Its constituents are students and its atmosphere that of a school. The instruction offered is, so far as courses and appliances are concerned, about as "practical" as it can be, and it should be of great value as a preparation for all grades of mechanical and technical work; but in precisely those points which are most indispensable to the training of a thorough mechanic, or, indeed, to any person who is to take a responsible position in mechanical matters, it is deficient. From this statement of the case we should be led to expect what experience confirms, namely, that in a considerable majority of cases the technical school graduate needs a supplementary apprenticeship before he is fit to take the position of foreman or superintendent. There are exceptions, of course. I have myself known one or two such cases.

Finally, anyone looking over the problem of technical training, and inquiring how its work must be planned so as to do for a young man the most possible in a given time, can see many things that would be desirable if practicable. For instance, it would be desirable if students could come with more of a good foundation of general education under them. We in the colleges echo the wish, but it sometimes seems as if every tendency were in the opposite direction. It would be a great step in advance if men would come to the higher schools mature enough to know what they can do and what they want to do. Then if instructors could only tell certain students that they have no business in a technical school and never will have—not roughly, but kindly—and give them some advice as to what they had better do; if, in short, there could be more *selection*, and the numbers to be handled reduced somewhat—everything could be done better. As things are now constituted and now tending, it does not seem as if much could be done in any of the above directions. How much difference it would make in the situation if the technical schools really tried to be *selective* is a question. The experiment is certainly impracticable under existing conditions, but one can hardly help wishing it could be tried. One thing is certain: minds cannot be trained by machinery, and in general, as our educational institutions become more crowded, instruction will certainly become and is now becoming more and more machine-like. If the time ever comes when the colleges and technical schools are less crowded, and when more men stop with an ordinarily good high-school education—a state of things which would have its advantages—there is no doubt but more will be accomplished in the line of making thinkers in both technical school and college. Either this must be the case, or evolution must work some change in the coming student, by virtue of which he will be led to reflect and think under conditions not favourable to the student of to-day.

GAS *V.* ELECTRICITY.*

After the very able exposition of "Gas *v.* Electricity" by the President of the Gas Institute (Mr. Denny Lane) this year at Belfast, I fear there is little ground for me to touch on the subject. I should like to reiterate, however, in as clear a manner as possible, the relationship in the cost of the rival lights to the consumer, *i.e.*, light for light. This has hitherto been stated more or less clearly, and sometimes with a certain vagueness on account of the technicality of the subject. Perhaps the following table will emphasise the information in as lucid a manner as it can be stated:—

Comparative Cost of Gas and Electric Light.†

Electric lighting at 6d. per Board of Trade unit.		Gas (16-candle) at 2s. per 1,000 cubic feet.				
		Ordinary open flames given by burners.		Standard Argand burner.	Regenerative lamp.	Incandescent gas light.
		As commonly used.	Adapted to pressure of gas and light required.			
Number of units said to be equivalent to 1,000 cubic feet of 16-candle gas.	Cost.	Candle-power per cubic foot of gas consumed.				
		1½ to 2	2½	3⅛	10	20
Allowed by Board of Trade } 10	5/-	3/10	2/4	2/0	-/8	-/4
Practical men estimate..... } 12½	6/3					
One-sided advocates say ... } 6	3/-					

It is thus that electricians compute (the 3s. 10d. against the 3s.) the cost of their light being "cheaper than gas." Their assumption of 6 units instead of 10 units, allowed by the Board of Trade as being equal to 1,000 cubic feet of gas, is a wilful playing with "standards of light." It is, however, done with the greatest *sang froid*. Were the gas industry to be as guilty of misrepresentation it could with all reason adduce the latest development in economical lighting by gas, viz., the incandescent light, which reduces the cost to one-sixth of our standard, or one-fifteenth of the cost of electric light. The fair way to put it, however, is: Gas standard, 2s.; electric light standard, 5s.—*i.e.*, electric light two and a-half times the cost of gas, light for light.

There are about 600 towns which may be expected to use the electric light, if it were a success commercially; but only 5 per cent. of these as yet have each a comparatively small installation. The average proportion of light in such towns is 2 per cent. electric light, and 98 per cent. gas light. Taking the proportion of electric lighting for the whole country, we find it would be 1 per cent., against 99 per cent. of gas light in use. This year 18 towns have applied to the Board of Trade for powers, against 24 the year before—out of the 300 to 400 which "intended" to apply. As the number of towns experimenting with the new light is in a decreasing ratio, this shows that it has reached its level, and that it now appears in its proper guise in the estimation of those who may adopt it, if not in that of the electrician and capitalist.

I would commend those towns about to adopt an electric light installation to note what was published a few weeks ago from the home of electric lighting—America—where it has got such a foothold; gas being three to four times the price paid in this country. It is said that "33 out of 56 electric lighting companies doing business in Massachusetts did not pay any dividend last year, while the average dividend paid for the year by the whole 56 companies (as many as are working in this country) was only 0·0235 per cent."

In these few sentences I have endeavoured to place before you the status of the gas industry in regard to its manufacturing and distributing plant, as well as to our rival in the field—electricity. The adoption of prepayment meters meets the case of a greater competitor—oil—for domestic lighting. It also would soon fail, so far as economy goes, were gas consumers alive to the fact that they could light their houses, even with ordinary open-flame burners, at least 30 per cent. cheaper than they do at present, by simply using burners properly adapted to their requirements. It is well

* Abstract of the Presidential Address by Mr. D. Terrace, read before the North of England Association of Gas Managers.

† [This table, which is anything but lucid as it stands, appears to be based on the cost of 3,333 candle-hours. It is referred to in our Notes.—Ed. *E.*]

Digitized by Google

known that gas of (say) double the quality we supply is often deteriorated to less than half its value by consuming it under high pressure and in small burners; whereas both it and poorer quality gas can be readily made to give greatly increased lighting power, according to the means taken to secure this.

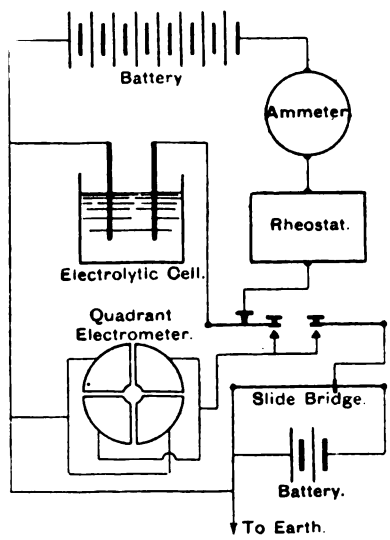
The future of electric lighting may be briefly summed up in the words of that great scientist, the late Sir C. W. Siemens, who said, when he was President of the British Association, in 1882-83: "Improved gas lighting may continue its rivalry with electric lighting, both as regards economy and brilliancy, and such rivalry must result in great public advantage."

POLARISATION OF PLATINUM ELECTRODES IN SULPHURIC ACID.*

BY JAMES B. HENDERSON, B.SC.

This investigation was begun about the beginning of February, 1893, at the instigation of Lord Kelvin, and was conducted in the Physical Laboratory of Glasgow University. The object of the investigation was to obtain the difference of potential between two platinum electrodes immersed in a solution of sulphuric acid immediately after the stoppage of a current which had been electrolysing the solution, and to find how this difference varied with a variation in the intensity of the current or in the strength of the solution.

Former experiments by Buff † and Fromme ‡ have given for the maximum polarisation with platinum wires of very small service in the electrolysis of dilute sulphuric acid 3·5 and 4·6 volts.



The cell used in the present investigation was a cylindrical glass vessel 10cm. in diameter and 12cm. deep. The electrodes were rectangular plates of platinum foil 7cm. long by 5·5cm. broad, and were stiffened by being mounted on rectangular frames made by bending glass tubing. The plates were immersed in the solution to a depth of 5cm., having their planes parallel and about 1cm. apart. There were thus 55 sq. cm. of surface of each plate wetted. To find the polarisation one of Lord Kelvin's quadrant electrometers was used, and by an arrangement described later, the breaking of the electrolysing current circuit and the switching of the electrodes on to the terminals of the electrometer were done simultaneously. Before switching as above, however, the needle of the electrometer was deflected by making a difference of potential between the pairs of quadrants, and this deflection was so adjusted by trial and error that, when the electrodes were switched on the needle was no farther deflected. For deflecting the needle of the electrometer a high resistance slide bridge was used. A difference of potential was maintained between its two ends, and the difference of potential between one end and the slider was used to deflect the needle, so that by moving the slider one way or the other the deflection could be increased or diminished at will. The electrolysing current was kept constant throughout each experiment, being measured by one of Lord Kelvin's electric balances, and adjusted by a rheostat. One terminal of the electrometer, one electrode, and one end of the slide bridge were connected together and then put to earth. The current for the electrolysis was got from eight large secondary cells, and the difference of potential between the ends of the slide bridge was maintained by two small secondary cells. The arrangement of keys can be understood from the diagram. By pressing the key k', connection was made between the slider and the unearthed quadrants, and when the key k was free the circuit was complete for the electrolysing current, but when k was pressed down the circuit was broken, and the unearthed electrode was connected to the unearthed quadrants.

The order of an experiment was the following:—

After standardising the electrometer by means of a Clark cell the electrolysis was started, and the unearthed electrode connected by a wire (not shown in the diagram) to the unearthed quadrants. The deflection of the needle thus produced, which showed the difference of potential between the electrodes, continued to increase steadily until, after the lapse of an interval of time depending on the strength of the current, it became constant. When this stage was reached the wire mentioned above was removed and the key k' pressed and kept down, thus making connection between the slider and the quadrants. The slider was then moved along until the deflection was nearly equal to that which would be given by the polarisation, and the key k momentarily pressed, thereby breaking the current circuit and connecting the electrode to the quadrants. An impulsive deflection immediately followed, unless the potential of the quadrants was equal to that of polarisation. If this deflection was negative (which indicated that the potential of polarisation was less than that of the quadrants) the slider was moved so as to reduce the potential of the quadrants below that of polarisation, thereby making the impulsive deflection positive, and then the experiment was continued as below. When the positive deflection was obtained its amount was noted, and the slider was moved so as to increase the steady deflection nearly up to the point on the scale reached by the impulsive one, and another trial then made. In this way, by watching the point reached by each impulsive deflection, and then increasing the steady one almost up to that point, the latter was increased until the former vanished—that is, until the potential of the quadrants was that of polarisation. The magnitude of this deflection was then noted, and the polarisation calculated from it. In these trials the key k was kept down only for about two seconds, just sufficient time to allow the extent of the deflection to be seen, and at least two minutes were allowed to elapse between one trial and the next.

After the maximum deflection had been reached a considerable interval of time was allowed to elapse, and then the key k' raised and k simultaneously lowered and kept down, and the rate of fall of the deflection noted. The above motion of the keys threw the slider off and put the electrode on to the quadrants, at the same time stopping the current. The deflection was therefore due to polarisation alone, and its rate of fall was therefore the rate of fall of the polarisation.

The results of one series of experiments are given in the accompanying table.

All the results point to the polarisation being constant with large electrodes, being independent of the strength of the solution and the intensity of the current. The variations in the figures do not occur in any order, and are all such as might be expected in experimental results of this nature. Some of the greatest variations were obtained in exactly similar experiments performed at different times.

The mean of all the values of the polarisation in this table is 2·09 volts.

The rate of fall of the polarisation depends on the time the current has been electrolysing the solution, and also on its intensity; but in every case the fall is very rapid at first, being in some cases as much in the first minute as it is in the next five minutes; and the fall in the first minute is never less than one-fourth of the polarisation.

Percentage strength of solution.	Strength of current in amps.	Deflection for Clark cell.	Deflection for polarisation.	Time the current had been passing. H.	Time the current had been passing. M.	Polarisation in volts.

ALTERNATE-CURRENT WIRING.*

BY W. D. WEAVER.

The following tables, calculated from Kennelly's formula,† give the increase of drop due to impedance in circuits carrying alternating currents. Each table is for a different frequency, as given: the first two vertical columns of a table give the gauge of wire, the horizontal column at the top the distance apart of the two wires of a circuit, and the other columns the coefficients by which the drop due to a continuous current should be multiplied to find the true drop if an alternating current is used. To lower the drop due to impedance it will be seen that large wires should be avoided. In inside work particularly a considerable saving of copper may often be made by dividing the feeders of mains into several circuits. The following method will enable the tables to be applied with an approximation sufficiently close for practical purposes:—

(1) By means of one of the usual formulæ, calculate, for the given lamps, amperes, or horse-power, the size of the wire (in circular mils) as if a continuous current were to be used, and from a table giving the gauge equivalent find the nearest corresponding gauge number.

(2) Enter with the gauge thus found that one of the following tables which corresponds with the periodicity used and take out the corresponding coefficient.

(3) Multiply the original circular mils by this coefficient and find the corresponding gauge again as above.

(4) Repeat the operation of (2).

(5) Multiply the original circular mils by this second coefficient and proceed otherwise, as in (3).

* From the *Electrical World.*

† $f = \sqrt{1 + \frac{p^3 \pi^2 r^4 (0{\cdot}5 + 2\log_e \frac{D}{r})}{\rho^2}}$ (Kennelly on "Impedance," *Transactions* of the American Institute of Electrical Engineers, April, 1893).

If thought necessary, a third or fourth approximation may be made by repeating the operations indicated in (4) and (5). The above rules and tables apply to alternating currents that can be represented by simple sine waves. If the current waves are of more complex type, the drop due to impedance will be increased. The above values are therefore minimum values. The tables are based on the assumption that the current density in the conductor remains uniform. With the frequencies used the error introduced by this assumption is negligible as relates to the calculation of impedances as well as to the increase of drop due to the unequal distribution of current in the conductor.

THE MEETING OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.*

The seventy-ninth meeting of the American Institute of Electrical Engineers was held at its headquarters in New York, on September 20, 1893, with President E. J. Houston in the chair. Some discussion was caused by the action of the Council in ordering to be printed, without reading, a Paper of a non-member of the Institute which had been read before another society. The Paper referred to was one by Dr. W. J. Morton on "A Brief Glance at Electricity in Medicine," which was read before the New York Electrical Society on May 17th. Mr. T. D. Lockwood protested, in vigorous terms, against permitting a Paper read before another society to be thus published at the expense of the Institute, and asked if the Editing Committee had consented to the publication of the Paper. While acknowledging the high scientific acquirements of Dr. Morton and the great value of the Paper itself, Mr. Lockwood challenged the right of the Council to thus establish a precedent for printing Papers of another society, or of non-members, in the *Transactions*, and at the expense of the Institute. The Chairman explained that Mr. T. C. Martin had asked Dr. Morton to prepare a Paper for the Institute, and that the authoritative character of the Paper in question was thought by the Council so great as to warrant its being printed in the *Transactions*. Mr. G. M. Phelps asked that the discussion be ruled out of order, and a motion was finally adopted to proceed to the reading of the Paper on the programme. Mr. D. McFarlan Moore read his Paper on "A New Method for the Control of Electric Energy," in which a vibrating device was described for regulating voltage. The apparatus consists of a vibrating armature, whose rate of vibration is controlled by approaching or receding the core of a magnet; at each vibration a circuit is made and broken, or the contact pressure is varied, although the author did not conclusively show that this latter principle entered. Aside from the author's explanation, it would seem that the reduction in voltage is caused partly by the magnet windings acting as a choking coil, and partly because the effective E.M.F. is reduced to the square root of the sum of the squares of its value at different times, these values varying from a maximum to zero. President Edwin J. Houston then delivered his Inaugural Address, the subject being "The Chicago International Congress," which dealt in a masterly manner with the work of the Congress, pointing out in what respects it succeeded and where it failed, and referred in glowing terms to the great accomplishments and magnificent possibilities of electricity. The address was received with great applause, and Mr. T. D. Lockwood, in his usually felicitous manner, moved a vote of thanks, which was seconded, and unanimously and cordially adopted. At the conclusion of his Address Prof. Houston called attention to the great desirability of standards of light and illumination, a matter upon which the Electrical Congress had arrived at no conclusion, and requested authority to appoint a committee composed of members having facilities for carrying on the necessary experiments, for the purpose of making a thorough and scientific investigation of the subject, in order that the institute may be able to submit a definite programme to electrical bodies throughout the world for discussion with a view to final adoption. He stated that Mr. Preece had consented on his part to co-operate in England with the Committee, and to undertake experiments with the same object in view. A motion granting the necessary permission to appoint and instruct a committee was later seconded and unanimously adopted. During the discussion on Mr. Moore's Paper the Chairman noticed Mr. Preece among the audience, and invited the distinguished honorary member of the Institute to a seat on the platform. Upon the conclusion of President Houston's remarks, Mr. Preece was asked to address the meeting, which he did in a graceful, pointed, and witty manner, which has established his reputation as one of the most effective and versatile speakers in the scientific circles of England. He referred to the great pleasure which he had derived from his latest visit to America, and also to the great professional benefit gained from it. He spoke of his proposition to co-operate with the Insti-

* From the *Electrical World.*

tute in its endeavours to establish units of light and illumination, and alluded in particular to the great desirability of establishing a unit of illumination. The address of Mr. Preece was in an especially happy vein, and left the impression with some that it was perhaps well for "Our Chauncey" that circumstances prevented the distinguished Englishman from coming into direct rivalry with him. Mr. C. P. Steinmetz brought to the attention of the Institute the desire of some fifteen members of the Institute at Lynn (Mass.) to hold local meetings at that place.

THE NEW BRUSH 125-ARC LIGHT MACHINE.*

In general appearance this machine does not differ materially from the usual type of Brush arc machine, but on close examination it shows some departures from the method of construction heretofore adopted. The machine has four poles, and the armature is cross connected, so that only one set of brushes is used with the usual three rings, each ring having eight segments. The magnet cores are of soft steel. The armature has been subjected to a special study in this machine, owing to the high voltage employed, and for the particular purpose of reducing the sparking at the commutator. In the old type of machine, it will be remembered, the shape of the sheet-iron pieces which make up the core was such as to make up a uniform cylindrical surface, as shown in the engravings, Figs. 1 and 2, which illustrate, respectively, a side and an end view of a portion of the old-style armature. In order to make the line of commutation as sharp as possible, the armature core plates of the new machine have been tapered off on both sides between each pair of the coils, presenting the appearance shown at A in Fig. 3. With this

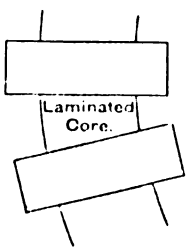

Fig. 1.

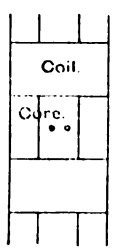

Fig. 2.

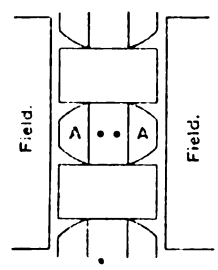

Fig. 3.

construction the result has shown that the sparking is greatly reduced. The armature is wound with 24 bobbins having 528 turns each, of No. 14 wire. Each of the field cores is wound with 1,560 turns of No. 8 wire. The whole machine weighs 9,000lb. has a 38in. by 44in. base, and is 4ft. high. These dimensions are smaller than those of the No. 8 Brush 65-lighter, which was 87½in. long. The total length of the new machine from pulley to commutator is 84in. The combination as it stands, engine and dynamo together, occupies a floor space 4ft. by 11ft. The machine is designed to give 6,250 volts at 525 revolutions, but the engine to which it is coupled, being designed for only 460 revolutions per minute, allows the dynamo to generate only 5,200 volts, equivalent to 100 lights. The external characteristic of this machine is highly remarkable, showing the perfection to which this type of apparatus has been brought. In a recent test made at the engine works of the Bullock Manufacturing Company, the output of the machine was varied between 4·29 and 12·1 amperes. The curve representing the amperes rises gradually up to a point represented by 9·4 amperes and then falls abruptly. The curve is almost an ideal one, and represents the great desideratum in an arc lighting machine, and one especially, in which the voltage is as high as it is in this case. The engine to which the dynamo is connected is of the well-known Willans type.

Gutta-percha.—A process has been invented by M. Rigole, of France, for extracting gutta-percha from the leaves and twigs of the *Isonandra dichopsis*. This process will, it is claimed, ensure an unlimited supply of gutta-percha in a few years' time, as it allows of the trees being utilised continuously during the whole period of their existence, instead of being cut down and destroyed for a single yield of gutta-percha, as is now done. An estate has been selected in the island of Pulo Obin, near Singapore, for the establishment of a plantation and factory. A process, having for its aim a similar prolongation of the tree-life, and invented by M. Sérullas, was described in *The Electrician*, Vol. XXIX., page 302.

* Abstract from the *Electrical Engineer* of New York.

OPENING OF THE DERBY ELECTRIC POWER STATION.

On Tuesday evening last, the 10th inst., the new electric power station at Derby was formally opened by the Mayor of that town. The site chosen for the generating station is close to the river, at the place where the Old Silk Mill formerly existed, and is well suited for coal and water supplies. When complete the station will be equipped with 13 engines, each driving a separate alternator, but at present only six of these have been fixed. The engines are of the vertical compound type, of from 50 to 100 H.P. They are supplied with steam at 130lb. pressure from Lancashire boilers fed with fuel by Vickers' mechanical stokers. The entire system of supply is by means of alternating currents, the very low frequency of 40 ∿ per second having been adopted throughout. The street lighting is by arc lamps, each of 2,000 c. p., arranged in series of 35 lamps. The public supply is on the high pressure sub-station system, provision having been made for ten transformer sub-stations. The feeders are at 2,000 volts, and the low pressure network is maintained at from 100 to 105 volts. The capacity of each sub-station is equal to 1,200 8 c.p. glow lamps. The station and distributing plant have been carried out to the designs, and under the superintendence of Messrs. Bramwell and Harris.

MUNICIPAL SUPPLY STATIONS, GAS ENGINES AND ACCUMULATORS.

The question of the connection of gas engines with electric supply is one which has often been discussed in these columns, but the following abstract from a Paper by a German author presents some figures which may be interesting for purposes of comparison:—

There can be little doubt that in many country towns the combination of gas with electric supply would increase the companies' revenues, and form the basis of a sounder business than the supply of gas for illuminating purposes is ever likely to prove under such circumstances. Information on this subject has been recently supplied by the Accumulatoren-Fabrik Hagen. The first point to note is the great increase in efficiency of gas engines of late years, in regard to which Herr von Oechelhäuser, a well-known authority on gas manufacture and use in Germany, in a Paper read recently, referred to the old, but now erroneous, rule that one cubic metre of gas per hour develops one horse-power; whereas at present quite small engines give one horse-power for 800 litres, and larger ones are guaranteed to evolve one horse-power per 650 litres. The improvement is enormous, and cannot fail to react on the use of the gas engine. And the second point of almost equal importance is the increase in the size of the engines, which renders a larger unit of supply possible than was formerly the case.

Take, as an illustration, the following case. In the town of Dessau is an installation, worked by Otto gas engines amounting to a total of about 180 H.P. In the year 1887 these engines used on an average 953 litres per horse-power-hour; in 1891 this had been reduced to 730, and in 1892 to 710 litres. As unit in this station is used a "Deutz" gas dynamo of 120 H.P., having a "Fritsche" disc-armature, which at 145 revolutions per minute uses a cubic metre of gas for 905 watt hours—that is, about 30 litres per 30-watt lamp-hour; and another German firm (Körting Brothers, Hanover) gives the same figure as the efficiency of its larger gas dynamos.

English practice differs so widely from German in the matter of electric supply that the cases taken as illustrations are often inapplicable in their present form; but they may be made, *mutatis mutandis*, to supply subjects for reflection to the British engineer. With this preface let us proceed to the pamphlet of the Accumulatoren-Fabrik Hagen.

In order to economise in copper as much as possible, says the *brochure*, it has been found necessary in large towns having distribution at 100 volts, either to make several complete stations independent of one another, or to make sub-stations with accumulators fed from the central station along special conductors, as in Düsseldorf and other towns lately described in *The Electrician*. The advantages possessed by the latter method are a saving in works costs, due to the smaller number of men employed and a saving in capital expense in boilers, &c., but these savings may be swallowed up in the cost of installing accumulators and charging mains, and in more or less heavy depreciation. The Accumulatoren-Fabrik therefore advocates the use of gas dynamos on the spot for the purpose of charging the cells placed at the sub-stations.

Digitized by Google

For the sake of working out some sample figures, the authors have assumed a town in which electric lighting is the rule and not the exception, and have taken as the basis of their estimates of plant capacity a load-curve which is an average best-load day of the towns Dresden, Magdeburg, Bremen, Karlsruhe, and Hagen. It is obvious that the use of dynamos without accumulators would necessitate an expenditure in plant represented by the maximum load, and although this does not necessarily mean working the machines generally at light load, and therefore inefficiently, as the authors seem to suggest (for there is such a thing as parallel running in daily use) the capital expenditure is certainly increased. The authors suggest the obvious advantage of running the machines all day on the cells at an approximately constant load, charging them up during the hours of light load, and discharging during the time of maximum demand.

Now this arrangement means a uniform demand for gas, and ensures therefore that it is produced as cheaply as possible ; and in a great and increasing number of cases the gasworks are owned by the local authority, and therefore gas is cheap ; the authors have therefore taken 2s. 4d. per 1,000 cubic feet as an average price, to which we must add that in England the cost of gas to a local authority when made and used by itself would probably be much lower than this.

The authors proceed to sketch out a scheme for the lighting of a town of about 70,000 to 150,000 inhabitants. They suppose two stations, each containing three gas dynamos of 120 H.P. each, two supplying current to a simple three-wire system, and one as reserve. These machines would be capable of supplying about 30,000 8-c.p. lamps at once, or about 45,000 wired. The stations are supposed to be about three-quarters of a mile apart, the feeders have 10 volts drop at full load, and the lamp-pressure is 110 volts. The plant at each station would be three 120 H.P. gas engines (one in reserve), three shunt dynamos, 110 volts 700 amperes (one in reserve), one battery, capacity 4,600 ampere-hours, charging current 662, discharging 1,060 amperes.

Using the dynamos as motors, no separate machine is necessary for the purpose of starting the large gas engines. Each station feeds to three points in the network. As regards salaries, &c., the gas and electricity works offices are supposed to be in common, and the gas manager is also manager of the electricity works, at an increased salary of £75 per annum. The lamps are supposed to burn 750 hours per annum, a low value. The capital expenditure for these stations is figured out at about £75,000 ; while if 10d. per Board of Trade unit be charged the interest on capital, after paying all expenses, would be about 17 per cent. ; at 8·75d. it would be about 13 per cent., and at 6d. apparently about 4 per cent.

This result should be sufficiently encouraging to induce gas engineers to make serious efforts to displace the steam engine in this work ; for although the figures may be unconsciously biased, there can be little doubt that the question is no longer one of "the dim and distant future," but must soon enter the field of "practical politics." The advantages of the gas engine are obvious : there is no smoke trouble, and the simplicity and cleanliness would gladden the heart of many a station engineer. Dr. von Oechelhäuser, in the Paper before alluded to, sums up the advantages as follows :—The small space occupied, the small amount of water used, avoidance of haulage of coal, absence of smoke, no danger of explosion, small capital expenditure both on account of land, cables, and electric plant and buildings ; small amount of attendance required, and the certain and convenient control of the output at all hours, owing to the rapidity with which engines can be started. Very many of our local authorities are now in the throes of doubt as to what system of electric lighting to adopt, and it is very probable that some of them might do worse than combine their gas with their electric light supply ; at all events, the question is worthy of serious consideration, and that the system has a great future before it in this country will probably soon be evident to engineers.

PARLIAMENTARY INTELLIGENCE.

A report has been made by the Board of Trade of their proceedings under the Tramways Act, 1870, and the Gas and Water Works Facilities Act, 1870, during the Session of 1893. The number of applications to the Board of Trade for Provisional Orders under the Tramways Act, 1870, made in December, 1892, was seven, viz., Birmingham Central (cable), Blackpool Corporation, Great Yarmouth, Hull, Manchester Corporation, Plymouth Corporation, and South Staffordshire. All these applications proposed the construction of new tramways, being, in every case except Great Yarmouth, in extension of, or in substitution for, lines already in use. The Birmingham Central, Hull and South Staffordshire applications were ultimately dropped by the promoters.

Four Provisional Orders were granted by the Board of Trade, viz., Blackpool Corporation, Great Yarmouth, Manchester Corporation, and Plymouth Corporation. The Blackpool and Plymouth Orders empowered the Board of Trade to grant a licence enabling the local authorities to work the tramways on being satisfied that the lines could not be leased at an adequate rent. In the case of the Great Yarmouth Order, the deposit money not having been paid into Court, the Board of Trade were unable to submit the Order to Parliament for confirmation. A Bill to confirm the other three Provisional Orders was introduced in the House of Commons on May 5th. Petitions were presented against the Blackpool and Plymouth Orders, but were subsequently withdrawn, and the Bill passed through the first House unopposed. In the House of Lords petitions were again presented against the Blackpool Order by the promoters of the Blackpool, St. Anne's and Lytham Tramways Bill, and against the Plymouth Order by the National Telephone Company (Limited). New clauses and other amendments were agreed upon between the parties, and the Bill received the Royal Assent on August 24th.

During the Session a Joint Committee of both Houses was appointed to consider and report whether the granted statutory powers to use electricity ought to be qualified by any prohibition or restriction as to earth-return circuits, or by any provisions as to leakage, induction, or similar matters ; and, if so, to settle the necessary clauses. The Joint Committee recommended a form of protective clause, which, with slight modifications, was incorporated in the Blackpool and Plymouth Orders in lieu of clauses previously inserted.

The Tramway Orders Confirmation Bill (No. 2), suspended from last Session, was proceeded with under the resolutions adopted in the previous Parliament. The Somerton, &c., Order was again petitioned against in the House of Commons by Mr. J. H. Thring. The case was heard by a Select Committee, who reported in favour of the confirmation of the Order, subject to a provision which they inserted as to the width of the road on which the tramway is to be laid. The Bill received the Royal Assent on March 28, 1893.

CITY INTELLIGENCE.

The Commissioners of Sewers.

THE TELEPHONE TUBES AGAIN : A LIVELY DEBATE.

Mr. J. HARRIS inquired whether it was true that the Electric Lighting Company had been using the telephone tubes they had laid down in conjunction with the electric lighting tubes.

Mr. GORDON replied that he had heard it mooted that they were being used *sub rosa*.

Mr. WALLACE asked whether *sub rosa* was a new technical term for telephone tubes.

Mr. HARRIS then moved that the question should be referred to the Streets Committee for investigation.

Mr. WALLACE said surely the executive of the Commissioners would prevent such a thing being done, but he protested against a fishing inquiry being instituted by a committee without there being some decided information forthcoming. If the Commissioners was being played with, and the officers had neglected their duty——

The CHAIRMAN reminded Mr. Wallace that there was no charge against any officer whatever.

Mr. WALLACE (continuing) said he declined to accept loose statements upon the *ipse dixit* of any member.

Mr. Deputy SCOTT : May I ask what *ipse dixit* means? Will Mr. Wallace tell me if it is a new technical term ?

Mr. MORTON said that in the first instance the tubes for telephone purposes were put down in a surreptitious manner, and without the consent of the Commissioners. He had seen the plans.

Mr. Deputy SCOTT declared that the Company told the Commissioners the purpose for which the tubes which had been referred to would be used. It was said that the tubes were to be used for the purpose of managing their lighting, and that they were necessary. But whatever had been done had been for the benefit of the public, and if the Commissioners could get the use of the telephone at half the price it would have accomplished a good thing on behalf of the citizens. Besides, the Company had power to put in these tubes, and if it had not been done the whole of the streets would have been pulled up a second time. That being so, he desired to know whether on both sides the public convenience had not been considered. The tubes had been absolutely set out in the plans sent in to the Commissioners. They were displayed in the second set of plans.

Mr. BERRIDGE remarked that the tubes referred to were not laid for the National Telephone Company. The Company which was carrying out the lighting was in communication with a new company which, it was said, was going to give the public cheaper telephones ; but the Company had managed to square the new Company, and take over the tubes. There was not much chance, he thought, of the public getting any great reduction in the charge that the Telephone Company made upon them. He agreed with the member who declared that the tubes in question were not shown upon the first plan ; and why ? he asked, simply to give them the opportunity of creating a monopoly.

Digitized by Google

Mr. SAYER pointed out that the Commissioners did not suppose that the Company was going to sell the tubes, which they had stated were to be used for the benefit of the lighting, but anything almost was better than having the streets pulled up again.

Mr. WALLACE moved that the question should be referred to the Engineers' Department for investigation.

The CHAIRMAN then put the amendment, which, on a show of hands, was lost. The matter was then referred to the Streets Committee.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 29, 1893.

Electric Railway Accidents.—The increasing number of accidents on electric street railway lines is causing attention to be strongly directed towards means for their prevention. While the newspaper press ascribes every accident to the "deadly trolly," as if the electric current were the cause, in all except very rare cases they result from the negligence or carelessness of people in crossing the track, or from collisions of the car, either through incompetence on the part of the motor-man or from derangement of the controller and brake. While the speed of electric cars is usually greater than that of horse cars, they are otherwise more difficult to avoid, the horses in the former instances answering somewhat as a guard. The Brooklyn city authorities are proposing that all cars shall be required to be furnished with a guard in front that will be almost in contact with the rails, and that the speed shall not greatly exceed that of horse cars. In view of a recent accident in Cincinatti where loss of control of a car on a steep grade resulted in the death of several people, the authorities propose that each car shall be required to be furnished with an air-brake.

The Underwriters' International Electric Association has issued some minor amendments to the rules adopted by it this spring, and adopted definitions for the word "approved" where used in the rules, which is recognised as a commendable departure. The rules of this Association have already been adopted generally by the fire insurance companies, and it is expected that in a short time no others will be in use in the United States.

The American Institute of Electrical Engineers at its recent meeting listened to a Paper entitled "A New Method for the Control of Electric Energy." It described a device for the regulation of voltage which is merely a vibratory bell mechanism in a vacuum.

The World's Fair authorities have just made public their awards, and from the meagre account at hand at the moment it appears that they include almost every exhibitor, but that special awards, not yet announced, will be made for special merit.

Electro-Synthesis.—Mr. S. B. Mulligan who has recently applied electrolysis to the synthesis of organic compounds on the lines already worked by Prof. Crum Brown and Dr. Walker in Edinburgh, has, says *Industries and Iron*, extended the organic compounds capable of electrolysis to other bodies than organic acids. Amongst these new bodies which are capable of electrolysis are ketones, sodium salts like that of malonic ether amides and nitro-paraffin derivatives. All these compounds are exceedingly weak acids, and their salts are very unstable. It is therefore interesting to know that they are capable of yielding synthetic compounds by electrolysis. The products obtained are the same as one would expect to be formed by the action of iodine on the sodium or silver compounds of the substances electrolysed. The yields from the iodine reaction are, however, generally better than those given by the electrical method, but in some cases the latter method has given rise to the synthesis of compounds when the iodine reaction has signally failed. The author is therefore, full of hope that a careful study of the conditions favourable to electro-syntheses of this kind will result in the new method forming a valuable adjunct to those already in the hands of organic chemists.

CORRESPONDENCE.

"NEW LAMPS FOR OLD"; AND THE CHICAGO LAMP TESTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Brooking's letter in your issue of October 6th shows that he has quite missed the point of my article which appeared in your issue for September 29th. Whether contractors should, or should not, have fitted up houses with more lamps, whether rooms which have been already wired and supplied with current are, or are not, sufficiently lighted are considerations wholly beside the points considered in the article in question. It was not better lighting that I advocated, but the production of the *same amount* of light for a less total yearly cost. And this I explained, for the reasons given, could be effected by the householder buying lamps marked for a lower pressure and lower candle-power than before, when he required to purchase new lamps. For example, if his house be supplied with 100 volts nominally, or practically with 101 volts, then he should in the future purchase not 100 volt 16-c.p. or 100 volt 8-c.p. lamps, as the case might be, but 97 volt 13-c.p. or 97 volt 6½-c.p. lamps.

Mr. Brooking says I advocated "over-running" glow lamps, but, as a matter of fact, I avoided the use of this word in the article because over running suggests "over walking" "over age," &c., and implies that the laws of nature, or an Act of Parliament, have decreed the particular pressure that must not be exceeded for each particular glow lamp. Whereas what particular glow lamp should be used to produce a given amount of light at a particular pressure is simply a matter of economy. The cost of the labour in exchanging lamps must, of course, be added to the price of the lamps themselves, and in the case of public halls where the lamps are supported at the end of long electroliers, the cost of this labour may be an important item, and will lead to the economical life of lamps being longer than in places where the lamps are easily accessible. But unless the lamps have been fixed in positions nearly wholly inaccessible, in which case the electrical adviser, instead of the lamps, must be changed to obtain economy, the economical life of lamps at the price now quoted (1s. 6d. a piece), will be far less than their actual life, with energy even as low as 4d. per Board of Trade unit.

As the only English member of Group IV. of the Chicago Electrical Jury, I feel bound, in justice to my colleagues in America, to give my reasons for thinking you mistaken in your editorial comments on the lamp tests which were started at the Exhibition at the beginning of September. You say, "Life tests of this sort, and with the arrangements for maintaining a perfectly steady pressure which have been adopted, can have nothing but a fanciful and fictitious significance, and will be no guide to either the engineer or the consumer, &c." Your objection to the pressure being maintained perfectly steady at each of the values specified by the makers of the lamps I do not follow, since perfect steadiness of pressure for many weeks appears to me to be one of the most important conditions to secure in lamp testing. Perhaps your objection is not to the pressure being maintained steady when the current is flowing, but to the lamps not being, as you complain in the earlier part of your criticisms, turned off occasionally, as in practice. But if that be your objection, is it not more imaginary than real, seeing that the programme of the tests states "at intervals (as small as convenient in the earlier days of the life test) each lamp will be removed from the test rack, placed on the photometer bench, &c.;" that is to say, the dynamo current flowing through each lamp will be interrupted at intervals to place the lamp on the accumulator circuit, or, in other words, each lamp will be periodically cooled as in practice.

"The maximum life under which a lamp can be tested will be about 1,130 hours," and that you criticise as too short. But at any of the present prices for electric energy the economic life of a lamp, even if it still cost 4s., would be

Digitized by Google

much under 1,000 hours, and at the price now quoted (1s. 6d. per lamp) the economic life is almost certainly under 500 hours. Why, then, is 1,130 hours too short a time to employ in the tests?

If the tests on the 360 lamps selected from the nine most important American types be carried out as the programme directs, then so far from the results being "no guide to the relative merits of the lamps when at work on ordinary lighting mains," they will furnish much information which not only American, but also English, electric-light engineers are most anxious to gain. For the time has come when England can no longer afford to disregard the behaviour of cheap foreign glow lamps. Is, for example, the 8d. Westinghouse stopper lamp, of which so many thousands are being used in lighting the Chicago Exhibition, as efficient as a lamp made of glass hermetically sealed? Which of the two very different makes of glow lamp supplied by the General Electric Company of America is the better? How much truth is there in the printed statement issued by the makers of the Novak lamp: "It absolutely maintains its *initial candle-power* at its initial efficiency throughout its entire life?"

All these and, I hope, other questions, such as Do lamps run on alternate-current circuits last as long as on direct-current circuits? will be answered by these tests if they be carried on in the way they have been commenced. Tables, it has been decided, will be drawn up by the jury showing the price of a candle hour for many periods of the life of each kind of lamp, using a number of different prices for a kilowatt hour and a number of different prices for each type of lamp. The preparation, under many difficulties, of all the arrangements to enable the programme to be carried out occupied Prof. Thomas and his little band of fellow-workers many weeks, while the supervision of the tests will entail long journeys to Chicago by Americans engaged elsewhere. I feel sure, Sir, that *The Electrician* is too generous not to withdraw its condemnation of labours undertaken by men fully as enthusiastic and untiring as the workers of Great Britain, and whose love of the old country makes them keenly sensitive to undeserved harsh criticism of its Press.—Yours, &c., W. E. Ayrton.

October 7, 1893.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

"Drum Armatures and Commutators."—This book, which is written by Mr. F. Marten Weymouth, and is the latest addition to *The Electrician* Series, is now ready, and will be sent direct by the publisher on receipt of the published price, 7s. 6d., or it may be obtained from any bookseller. A prospectus will be forwarded on application.

Tenders Invited.—It will be seen by our advertisement columns that the Postmaster-General desires tenders (A) for the supply of red fir telegraph poles, to be delivered in London, King's Lynn, or Sutton Bridge, and at Northumberland Dock (River Tyne), West Hartlepool, Hull, or Grimsby; and (B) for creosoting the poles. Forms of tender, containing all particulars, to be obtained on application to Mr. Chas. E. Stuart, Controller of Stores, Telegraph-street, London, E.C., and tenders must be in by noon on the 30th inst.

——— The Rivers Committee of the Manchester Corporation are prepared to receive tenders for supplying and fixing electrical plant, vertical engine dynamos, accumulators, and all necessary connections and appliances required to light the sewage works at Davyhulme. Copy of specification, and all particulars, may be obtained from Mr. John Allison, city surveyor, and tenders must be sent to the Chairman of the Rivers Committee not later than Tuesday next, the 17th inst.

——— The Cardiff Corporation are prepared to receive tenders for the manufacture and delivery of electric light cables, &c., which must reach the Town Clerk on or before Monday next.

——— The Larne Town Commissioners will meet specially on Friday, the 20th inst., to consider any tenders that may be sent in for lighting the town for three years by gas or electricity.

Tenders Accepted.—The tender of Messrs. E. Houghton and Son, Stroud Green, N., has been accepted by the St. Pancras Vestry for the erection of new additional buildings to the electric light station in the Euston-road, the amount of the tender being £1,876. 4s.

Appointment.—The Kingston Town Council have appointed Mr. J. E. Edgcome resident engineer and manager at the electric lighting station, at a salary of £156.

Removal Notice.—Messrs. Lund Brothers and Co. have removed to 123 and 125, Oxford-street, W.

Liquidations.—Creditors of Abell's Electrical Engineering Company (Limited) are desired to send particulars of their claims to the liquidator, Mr. F. W. Marsh, Bank-chambers, Hardshaw-street, St. Helens, on or before November 15th.

——— A general meeting of Woodhouse and Rawson (Ltd.) is to be held in Room 434, at 11, Queen Victoria-street, E.C., on November 8th, at 4 p.m., for the purpose of passing an extraordinary resolution, directing as to the manner in which the books, accounts and documents of the Company, and of the liquidators, shall be disposed of.

——— A petition has been presented for the winding up of the Ipswich Electricity Supply Company (Limited), and is down for hearing on the 25th inst. at the Royal Courts of Justice, Strand.

Bankruptcy.—Under a receiving order granted on May 4th last against Knud Sando, described as a commission merchant, of 52, Wool Exchange, E.C., accounts have at length been submitted showing liabilities £32,944, of which £9,097 will probably rank, with assets £8,204. From the observations of the official receiver (Mr. A. H. Wildy), and the statements of the debtor, it appears that in 1879 he was in New Zealand as a partner in a firm of general merchants, and in that year the firm executed a deed of assignment for the benefit of creditors, who ultimately received a dividend of about 7s. in the pound. About five and a-half years ago he came to England to organise a company for colonisation purposes, and about a year later he began business, without capital, at 52, Wool Exchange, Coleman-street, E.C., as a general commission merchant, his business being chiefly the development and sale of patents and inventions. In December, 1890, the debtor states he began trading as a manufacturer of electrical appliances, which he carried on at Appold-street, E.C., and subsequently at Richmond, Surrey. In December, 1891, the Central Electrical Company (Limited) was registered, with the object of acquiring and carrying on the business last mentioned. The Company, however, did not go to allotment, and the debtor states he continued the business for his own account until February, 1892, when, having to go abroad on other matters, it was closed at a loss to him, as he estimates, of £3,000. He attributes his present insolvency to "losses in promoting the General Phosphate Corporation and loss of business through having to go to Canada in 1892 to assist this Company."

Dissolutions of Partnership.—The partnership between Charles Henry Freedman, Harrington Edward Hodson Wyman, and Frank West Suter, carrying on business as Frank Suter and Co., electrical engineers and contractors, of 66, Berners-street, has been dissolved, and the business will be in future carried on under the same name by the two last-named partners.

——— Messrs. Samuel Fynn and Charles Edward Stuart McCann, carrying on business as electrical engineers at 670, Commercial-road, E., have dissolved partnership, all debts to and from the late firm being paid by the former.

Incandescence Lamps.—The Edison-Swan Company announce a reduction in the price of their extra special lamps, in addition to that of their ordinary and special lamps, particulars of which appear in our advertisement pages.

Electric Lamps for Policemen.—Trial is being made at Dundee of an electric lamp constructed for the use of policemen, and the result of the experiment seems likely to lead to the old oil lamp being superseded by its modern rival.

Messrs. Paterson and Cooper.—We learn that this firm, who have been for several years on the Admiralty List for general fittings, have now been placed on their list for dynamos.

Messrs. J. G. Statter and Co.—We are informed that this firm have secured the contract for the electric lighting of the Royal Exchange.

Messrs. Nalder Bros. and Co.—This firm request us to state, with reference to a "Trade Note" in last week's issue, that their friend, Mr. N. F. Nalder, has never had any business connection with them.

Congdon *v.* Sambidge and Sons.—This case was heard this week at the Westminster County Court before Judge Lumley-Smith and a jury, and was brought to recover damages for breach of contract. The defendants were the well-known manufacturers of gas and electric light fittings at Birmingham, and the plaintiff was appointed

Digitized by Google

to act as their London agent. He said that he was insufficiently supplied with samples of the defendants' goods, and had been unable to obtain repeat orders for them on account of inferior manufacture, and was therefore compelled to put an end to the arrangement. The defendants generally traversed the plaintiff's evidence, and after hearing counsel and witnesses on both sides the jury found for the defendants with costs.

THE METRIC SYSTEM IN THE UNITED STATES.—As an indication of the growing favour of the metric weights and measures in the United States, it is interesting to note that at a meeting of the Board of Managers of Engineering Societies, recently held in Chicago, it was resolved that illustrations, to be drawn to scale, should bear the metric scales.

FORTHCOMING SCIENTIFIC BOOKS.—The following books are announced by Messrs. Macmillan and Co. :—"The Theory of Heat," by Thomas Preston, with illustrations ; "Researches on the Propagation of Electrical Force," by Prof. Heinrich Hertz, of Bonn, authorised translation by Prof. D. E. Jones, with preface by Lord Kelvin, P.R.S., illustrated ; "A Text-book on Electro-Magnetism and the Construction of Dynamos," by Dugald C. Jackson, Professor of Electrical Engineering, University of Wisconsin. The Cambridge University Press announce : — "The Steam Engine and other Heat Engines," by J. A. Ewing, F.R.S , Professor of Mechanism and Applied Mechanics in the University of Cambridge. The Cambridge University Press are also about to publish a series of Natural Science Manuals which will cover a wide field, some of the books being adapted for beginners, whilst others will deal with special topics, and will be useful only to more advanced students. The series will be divided into two sections, a Biological and a Physical. The volumes of the Physical Series already arranged for include three by Mr. R. T. Glazebrook, F.R.S., Assistant Director of the Cavendish Laboratory, on "Light and Heat," "Electricity and Magnetism," and "Mechanics and Hydrostatics" ; these will be elementary text-books, based on the Practical Courses of Physics for Medical Students at the Cavendish Laboratory, The volume on "Light and Heat" is in the Press, and the other volumes are in preparation. Messrs. Charles Griffin and Co.'s announcements include :—"A Text-book of Physics : including Properties of Matter, Heat, Sound, and Light, Magnetism and Electricity," by Dr. J. H. Poynting, F.R.S., Professor of Physics in the Mason College, Birmingham, and J. J. Thomson, F.R.S., Professor of Experimental Physics in the University of Cambridge ; "Gas, Oil and Air Engines : A Practical Text-book on Internal Combustion Motors without Boiler," by Bryan Donkin, with illustrations ; "Engineering Drawing and Design : A Practical Manual for Engineering Students," by Sidney H. Wells, Principal, Battersea Polytechnic Institute, late of Dulwich College ; "Applied Mechanics (An Advanced Text-book of)," by Prof. Jamieson, Glasgow and West of Scotland Technical College, with very numerous illustrations. Messrs. Crosby Lockwood and Sons have in preparation and in the press :—"The Practical Engineer's Year-book for 1894, comprising Modern Engineering Formulæ, Rules, Tables, and Memoranda, in Civil, Mechanical, Electrical, Marine, and Mine Engineering," by H. R. Kempe ; "Tramways : Their Construction and Working, embracing a Comprehensive History of the System, with an exhaustive Analysis of the various Modes of Traction, a description of Rolling Stock, and details of Cost and Working Expenses" (with plates and other illustrations), by D. K. Clark, new edition, in one volume, rewritten and revised. "The Electrician" Printing and Publishing Company will publish Mr. G. S. Ram's book on "The Incandescent Lamp and its Manufacture" early next month.

"INTENSE BLACK" INDIAN INK.—We have received from Messrs. George J. Poore and Co., of Liverpool, a bottle of their "intense black" Indian ink, which we find runs freely, dries quickly, and is quite indelible. This ink seems admirably suited for drawings for reproduction by line "process" blocks.

BERWICK.—The electric light is being introduced into the border borough by several of the local tradesmen, who are fitting up private installations.

BO'NESS.—At a meeting of the Bo'ness Dock Commissioners last week the question of the electric lighting at the dock came up again on a motion that the finding come to at a recent meeting of the Commissioners against the introduction of the electric light on the ground of expense should be rescinded. The motion was, however, lost.

DUNDEE.—Messrs. William Fergusson and Sons, of Dudhope Works, North Tay-street, when considering the plans for the rebuilding of their burnt-down premises, decided to introduce the electric light, and the plant has just been installed by Messrs. Lowdon Bros., working from specifications drawn up by Messrs. Urquhart and Small. The dynamo is driven by a double cylinder compound vertical engine, made by Messrs. G. E. Belliss and Co., Birmingham, and indicating about 70 H.P. It is coupled direct to an Elwell-Parker dynamo running 320 revolutions a minute, and capable of lighting 700 lamps of 16 c.p. each. The current is led from the dynamo to the main switchboard on the wall of the engine-room. On the switchboard is an automatic cut-in, so that if by any mischance the main circuit should become disconnected, or the engine and dynamo be stopped, a number of lights would be instantly turned on in each department from the Corporation circuit. The Corporation circuit will also be in use before and after the work starts, when only a small number of lights is necessary. The switching-off of the main current in itself automatically turns on the Corporation circuit.——The demand for the electric light from the Corporation supply has been steadily increasing since the works were completed. Of the 6,000 lamps which the present power can supply, some 4,000 have been applied for, and are now being supplied, and it is expected that the remainder will soon be in use.

EDINBURGH.—Messrs. A. Whitelaw and Son, electrical engineers machine makers and general engineers, of Edinburgh, have introduced electricity into their works for lighting purposes with great success. Hand lamps have been fitted up in such a manner that they can be moved about from place to place to suit the convenience of the workmen. A Tangye 8-H.P. gas engine, used for running the machinery in the works, drives the dynamo, which is of special construction, manufactured by the Messrs. Whitelaw. It is calculated that the new light, allowing for interest on capital expenditure, will cost less than the same number of gas burners, whilst the light is, of course, immensely superior.——The Corporation have purchased a site in Dewar-street as a central station for the installation of electric light about to be introduced into Edinburgh.

GLASGOW.—The Tramways Committee of the Corporation reported at the last meeting of the Town Council that they had resolved to ask Mr. Arnot, the city electrical engineer, to submit a statement showing the price at which the electrical energy could be supplied to batteries for the electric haulage of the cars, and also the cost of laying down and superintending the dynamos and other plant required for charging the batteries from five of the car depots now being erected by the Corporation. The minutes were adopted.

HANLEY.—The Town Council at their last meeting empowered the General Purposes Committee to obtain separate tenders for the electric light wiring and fittings required in all the buildings of the Corporation, and to make application to the Local Government Board for permission to borrow the money required for such work. Under the Council's contract with the Brush Company, the Corporation had the option of determining within twelve months of the date of the contract whether the Company should provide the fourth set of generating plant, viz., boiler, engine, and dynamo, at a cost of £1,800, or expend that amount in electric light, street mains, and appurtenances at the scheduled prices named in the contract ; and the Council have decided on the latter alternative.

KILLARNEY.—The question of the public lighting still remains unsettled. It will be remembered that the gas lessees and the electric light company recently tendered for the lighting of the town, the former at £92. 10s., and the latter at £55, and a majority of the Commissioners gave the contract to the gas people, notwithstanding the difference between the tenders. The electric light company allege informality in the proceedings, and have served a notice on the Town Clerk and the Commissioners' solicitor, cautioning them not to perfect the contract for the gas. They have also served notices on two of the Commissioners to refrain from voting on the lighting question, they being shareholders in the gas company. Since the service of these notices the Commissioners have not met in sufficient numbers to form a quorum, although meetings have been called two or three times.

LIVERPOOL.—The Water Committee of the Corporation have decided to recommend the City Council to approve a supplementary estimate of £1,000 to provide telephonic communication and other electrical appliances between Liverpool and Lake Vyrnwy, and between Liverpool and the Rivington Reservoir.

LLANDRINDOD WELLS.—At a special meeting of the Local Board, on Friday, a discussion took place on the subject of introducing electric light to the district, and, at the request of the Board, the Clerk gave an account of the system adopted at Dolgelly, North Wales, which he had lately seen in operation. It was generally considered very desirable that steps should be taken to introduce the system, if possible.

LYTHAM.—A scheme for the electric lighting of Lytham has been laid before the Improvement Commissioners by Mr. J. Harding, C.E., but the Commissioners have decided to take no action in the matter.

NANTWICH.—The Local Board have had under consideration the question of increasing the number of electric lamps they use ; but although the contractor who supplies the current offered to increase

Digitized by Google

it five-fold at little more than the present cost, the Board were afraid this might be only the thin end of the wedge, and would probably lead to the formation of another gigantic monopoly, and so resolved to remain illuminated by one lamp instead of increasing the number to five.

NORMANTON.—The Local Board having failed to obtain from the gas company more reasonable terms for the gas consumed by the public lamps, a committee has been appointed to inquire into and report on the best method and the cost of lighting the town by electricity.

RADCLIFFE.—The Local Board have appointed a Sub-Committee to consider the question of adopting the electric light in the district.

SOUTHWARK.—The St. Olave's Board of Works have decided to have their new offices lighted by electricity.

SUNDERLAND.—The Borough Surveyor has received instructions from the Highways Committee of the Corporation to advertise for tenders for laying the outdoor plant in connection with the electric lighting scheme.

WHITEHAVEN.—At the last meeting of the Town Council and Harbour Trust, the seal of the Board was affixed to a bond for £800, which was lent on account of the Electric Lighting Order by a private individual for six years at 3½ per cent.

YEADON.—A meeting of owners and ratepayers of Yeadon, convened by the Local Board, held on Tuesday, in the Town Hall, passed a resolution authorising the Local Board to adopt a system of electric lighting for the township.

COMPANIES' MEETINGS AND REPORTS.

Brazilian Submarine Telegraph Company (Limited)

The following is the report of the Directors for the half-year ended June 30, 1893, to be submitted to the fortieth ordinary general meeting, to be held in Room 174, Winchester House, E.C , on Wednesday next, October 18th, at 12 noon :—

The revenue for the half-year ended June 30, 1893, amounted to £106,859. 18s. 2d., and the working expenses to £40,580. 1s. 5d. After providing £12,880 for debenture interest and sinking funds, and £1,367. 8s. 1d. for income-tax, there remains a balance of £52,032. 8s. 8d. ; to this is added the sum of £4,000. 18s. 1d. brought forward from December 31st last, making a total of £56,033. 6s. 9d. A quarterly interim dividend, amounting to £19,500, has been paid, and £7,000 transferred to the reserve fund, increasing that fund to £638,675. 8s. 6d. The Directors now recommend the declaration of a final dividend of 3s. per share, making, with the interim dividends, a total dividend of 6 per cent. for the year, and also the payment of a bonus of 1s. per share, both free of income-tax, which together will amount to £26,000, leaving a balance of £3,533. 6s. 9d. to be carried forward. The dividend and bonus will be payable on the 19th inst.

On July 31st last the sum of £17,700 was transferred to pay off the 177 bonds of the 1884 issue, drawn for redemption in April last. This repayment reduces the debenture debt to £93,700.

The receipts for the half-year include the sum of £1,500 dividend to December 31, 1892, on the Company's shares in the African Direct Telegraph Company (Limited).

The Directors, with much regret, have to report the death, on May 7th last, of their esteemed colleague, Sir James Anderson. At the invitation of the Directors, Sir John Pender, G.C.M.G., M.P., has joined the Board, and accepted the Chairmanship of the Company.

Under a contract dated June 17, 1893, between the Portuguese Government and the Telegraph Construction and Maintenance Company (Limited), the Eastern Telegraph Company (Limited) and this Company are entitled to a prolongation for ten years of their respective privileges under existing Portuguese concessions. By arrangement with the companies concerned your Company has secured a considerable interest in the cable recently laid between Lisbon and the Azores under that contract.

The various sections of the Company's line are in good working order.

Mr. J. Denison Pender and Mr. Frederick Youle retire at this meeting, and being eligible for re-election as Directors offer themselves accordingly. The retiring auditors, Mr. Henry Dever and Mr. John Gane, desire to offer their respective firms, Messrs. Deloitte, Dever, Griffiths and Co., and Messrs. Gane, Jackson and Jefferys, for election as auditors to the Company.

NEW COMPANIES, STATUTORY RETURNS, &c.

[*In addition to the information given under this heading, detailed particulars of many of the Companies whose returns appear below will be found in* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK, 1893, pages 320-348, *&c., &c.*]

SWAN AND HARRISON SMELTING COMPANY (LIMITED).—This Company was registered on October 3rd, with a capital of £30,000, in £5 shares, to acquire, take over as a going concern, and carry on the Roma Smelting Works, situate at La Union, near Carthagena, in Spain, now carried on by Arthur Harrison. The subscribers include J. W. Swan, Lauriston, Bromley, Kent, electrical engineer.

BABCOCK AND WILCOX (LIMITED).—The annual return of this Company, made up to September 13th, has been filed. The whole nominal capital of £240,000, divided into 10,000 £6 per Cent. Cumulative Preference and 14,000 Ordinary shares, of £10 each, has been subscribed for and allotted. Of this, 3,333 Preference and 4,666 Ordinary shares were issued as fully paid, while upon the remaining 6,667 Preference and 9,334 Ordinary the full amount has been called and £160,010 paid.

BICKLE AND CO. (LIMITED).—The first annual return of this Company, made up to September 20th, has been filed. Out of a nominal capital of £50,000, in £10 shares, 2,021 have been taken up, of which 1,000 were allotted to the vendors as fully paid. Upon the remaining 1,021 shares the full amount has been called, resulting in the payment of £10,050, leaving £160 unpaid.

CHILI TELEPHONE COMPANY (LIMITED).—The annual return of this Company, made up to August 16th, and recently filed, shows that 44,000 of the 50,000 shares of £5 each have been taken up, the full amount called, and all calls paid.

CHLORIDE ELECTRICAL STORAGE SYNDICATE (LIMITED).—The annual return of this Company, made up to July 28th, has been filed. The nominal capital is £262,500, divided into 110,000 "A," 140,000 "B," and 12,500 Founders' shares of £1 each. 65,230 "A," 100,000 "B," and 12,500 Founders' shares have been taken up, of which 45,000 "A," 100,000 "B," and all the Founders' shares were allotted as fully paid to the vendors. The full amount has been called and paid on the remaining 20,230 "A" shares.

COLUMN PRINTING TELEGRAPH SYNDICATE (LIMITED).—The recently-filed return of this undertaking shows that out of a nominal capital of £25,000, divided into 500 shares of £50 each, 229 have been taken up, of which 100 are considered as fully paid. Upon the remaining 129 shares the full amount has been called, resulting in a payment of £5,550, while £900 is still in arrears.

CITY NOTES, &c.

A. U. ALCOCK ELECTRIC LIGHT AND MOTIVE POWER COMPANY (LIMITED.)—The seventh half-yearly meeting of this Company was held at the offices, Russell-street, Melbourne, on August 31st. Mr. W. J. Mountain presided. The Directors' report showed that the revenue for the last six months, compared with that for the corresponding period last year, showed an average increase of over £150 monthly, while the working expenses had been reduced by over £102 per month. The profit made during the last 10 months amounted to £289, which was considered highly satisfactory, as that period embraced the summer months, when the demand for current was lightest. The Chairman in referring to the Company's position and the depression, said that it was highly satisfactory to note that the revenue had improved steadily, and had doubled since 1889, as it now amounted to £851. 18s. 2d. In 1889 the profit was only £111, and this year it had reached £289. During the period under review the machinery was continually working throughout the 24 hours of each day and in consequence the Company's profits were nearly trebled, and the public could secure a supply of current at any hour of the day. This latter factor, together with the meter system, had done much to popularise the use of the electric light. With an increased output the efficiency of the central station had improved, as better results were obtained from the quantity of fuel consumed. Thus, although the output was increased 43 per cent., the consumption of coal only increased 28 per cent. These results, however, were only being obtained by practising strict economy and improving the efficiency of the machinery wherever possible. The demand for light had been more than was expected since July 1st, and the custom had increased to the extent of 649 16-c.p. lamps, with prospects of many more being added during the next few months. The Directors' report was adopted, and Mr. Simon Fraser, M.L.C., and Mr. A. U. Alcock were re-elected Directors.

BRITISH VOLTA ELECTRIC GLOW-LAMP COMPANY (LIMITED).—A prospectus has been issued this week, offering for subscription 1,600 out of a total of 2,000 shares of £1 each, the remaining 400 being issued to the vendors as fully paid. The prospectus states that the object of the Company is to make and supply cheap and good incandescent lamps, works for their manufacture being about to be established near London. The Directors anticipate that, even when selling good lamps at an average price of 1s. each, a dividend of over 30 per cent. would be earned on the subscribed capital.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended October 8th were £813, as against £859 for the corresponding period of last year, being an decrease of £46. The total receipts for the half-year amount to £11,262, against £10,853 in the corresponding period of 1892, being an increase of £409.

DIRECT UNITED STATES CABLE COMPANY (LIMITED).—The Board have resolved upon the payment of an interim dividend of 3s. 6d. per share, free of income-tax, being at the rate of 3½ per cent. per annum, for the quarter ended September 30, 1893, such dividend to be payable on and after the 24th instant.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this Company for September amounted to £23,600, and from January 1st to September 30th to £203,600. In the corresponding months of 1891 and 1892 the amounts were £213,400 and £199,600 respectively.

RICHMOND (SURREY) ELECTRIC LIGHT AND POWER COMPANY (LIMITED).—We are requested to announce that this Company went to allotment on the 10th inst.

SUBMARINE CABLES TRUST.—Notice is given that on and after October 16th, the sum of £1. 15s., on account of the coupon due

Digitized by Google

October 15, 1893, will be paid by Messrs. Glyn, Mills and Co., of 67, Lombard-street, between the hours of 10 a.m. and 2 p.m. The coupons should be left with the bankers for examination four clear days before payment.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended October 6, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,435.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 805.—Vol. XXXI. FRIDAY, OCTOBER 20, 1893. PRICE FOURPENCE.
Annual Subscription (U.K.), 19/6

NOTES.

We greatly regret to learn that Prof. Von Helmholtz, after escaping unhurt from riots, fire, railway accidents, tornadoes, and other perils incident to a visit to Chicago, met with a rather serious accident on board the steamship "Saale" during his return voyage. He fell down a companion ladder, and sustained injuries to his head. He was conveyed to the town hospital at Bremen on his arrival. His wife and daughter were with him. The condition of Prof. Von Helmholtz, the *Standard's* Berlin correspondent telegraphs, was somewhat better on Wednesday, but much rest and great care in nursing will be required before the eminent *savant* can be restored to his usual health. In reply to our inquiries yesterday afternoon we learned by telegraph from Dr. Goering, of Bremen, and from Charlottenburg, that Prof. Von Helmholtz is better.

In congratulating the inhabitants of Blackpool on their advanced municipal politics, Lord Kelvin, inaugurating the new supply station and public lighting, recommended that municipal corporations should take into their own hands everything which they could do efficiently for the good of the town, but they should not enter into transactions with distant places. Telephones and railways, he thought, should be acquired by the Government; but, for another reason, namely, that that which private companies could not do well, because of conflicting interests, was best done by the State. These two reasons might easily be exchanged; they have nothing in common with each other; and either they are no real reasons, or they may both be applied together. If Socialism is to come it does not matter much about reasons, but when the manufacturers and merchants, who have by their individual enterprise built up the commercial fortunes of this country, are invited to become vestry officials or Government clerks it will be time enough for them to consider whether it is a country worth living in. A further question, which may come too late, will be—Can the country get on without them? How long would telegraphs have been delayed if it had remained for the Government to start them, especially when an official statement was made in reply to an offer of an electric telegraph, that no improvement on the semaphore was wanted?

The daily papers have been discussing the "cheapening of electric light" in consequence of the reduction of the price of lamps. Prof. Ayrton has clearly shown in his recent article in these columns that, indirectly the smaller cost of the lamp allows a further economy by making it worth while to run at a higher efficiency. Experience alone can show to what extent lamps can thus be over-run, to use a common but not accurate expression. It is no doubt true that a 97-volt 6½-c.p. lamp on a 100-volt circuit will give about 8 c.p., and a 97-volt 13-c.p. lamp will give about 16 c.p. at first, but it is probable that the deterioration will be more rapid, and that the economy will therefore be somewhat reduced. Neglecting this over-running for the present, we give below a simple statement of the effect of reducing the price of lamps from 3s. 9d. to 1s. 6d., assuming that the life, as heretofore, will be about 1,000 hours, and that an 8-c.p. lamp consumes one supply unit in 30 hours.

Price of a supply unit.	Cost of supply for 1,000 hours.	Total cost.		Reduction per cent.
		Lamps at 3s. 9d.	Lamps at 1s. 6d.	
8d.	22s.	25s. 9d.	23s. 6d.	8·8
6d.	16s. 8d.	20s. 5d.	18s. 2d.	11·0
4d.	11s.	14s. 9d.	12s. 6d.	15·2

This is equivalent to a reduction in the price of supply to 7⅓d., 5⅓d., and 3·4d. respectively.

In another column will be found extracts from *The Times* on the subject of the subsidising by the Queensland and New South Wales Governments of the submarine telegraph cable just completed from Queensland to New Caledonia by the Société Générale des Téléphones, of Paris. The action of these Colonies is greatly to be regretted, as being opposed to Colonial and Imperial interests, and as tending to retard the establishment in British hands of direct submarine telegraph communication between Australasia and North America. Sir George Dibbs' defence of the position taken up by the New South Wales Government is lame in the extreme; and is completely controverted by the Marquis of Ripon's letter on the subject. It should be pointed out that it is quite misleading to call the cable in question the first section of a Pacific Cable, because the Imperial Government and most of the Colonies interested would certainly not subsidise a line which would be, in the event of political complications arising, completely under French control.

We print, this week, an addendum to Lord Kelvin's British Association Papers on the Piezo-electric effect in

Digitized by Google

crystals and at the contact of dissimilar metals. The Papers deal with an electrification due to pressure, or, rather, to unequally-distributed stress. In the dielectric crystal all that is necessary is a certain space variation of stress; but, as pointed out by Prof. FITZGERALD in the discussion on the two Papers, this is not sufficient to produce the effect in a system of dissimilar conductors. For the latter, owing to the gradual distribution of an equalised potential on account of conductivity, will require both a space variation and a time variation also. It is interesting, probably only from a theoretical point of view, to discover that the analogue of a thermo-pile can be constructed with, not difference of temperature between the junctions, but differences in the time rate of variation of the pressures at those junctions.

SOME curious experiments upon glow lamps have been described to us by Mr. A. A. C. SWINTON. By means of a high-frequency alternator, and a condenser formed out of a thick plate of glass and a couple of wire-ends, it was possible to raise an ordinary 100-volt glow lamp to full incandescence. The explanation which Mr. SWINTON offers is that the current consists of very brief intervals of enormous current alternating with longer intervals of practically no current. He observes that with a steady pressure of 100 volts the 5-c.p. lamp would expend 25 joules in every second, at a steady rate of 25 watts. With a high-frequency current of 100,000 $\sim$ per second, and 10,000 volts, it is clear that each pulsation would be required to produce 0·00025 joule, and to pass only 0·000000025 coulomb, in order to develop the same energy per second. The average current in the lamp during any one impulse would be as great as 25 amperes; but each impulse would be followed by a period of inactivity 999 times as long, making the average current in the complete second only 0·0025 ampere. The thermal capacity of the filament would prevent its temperature varying in the same ratio as the extremely variable power, and would cause it to emit a practically steady light. In the same way, for example, we might apply a transient force of many millions of pounds to the rim of a flywheel, while causing it to turn only with the normal speed which a steady force of a hundred pounds would produce.

THE explanation previously put forward by Mr. SWINTON, and we believe at an earlier date by Mr. SWINBURNE, was that the inductance of the current elements in the filament on one another is, with very high-frequency pressures, so enormous that the current flows entirely through only the outermost skin of the conductor. The effective resistance of the filament might in this way be raised many hundreds of times above its steady value. The advantages of this explanation are, chiefly, that it does not require that the current-impulses shall be interrupted by such long periods of inactivity, for the same effect might occur with a sufficiently frequent simple harmonic pressure, and it does not require so great an instantaneous value of the current. But Mr. RIMINGTON has calculated the increase of resistance, and finds that the frequency would have to be enormous. If there is no skin effect it is difficult to see how 25 amperes can be passed through the human body, although it is said that a very much greater number of amperes is produced at the instant of some Leyden jar discharges which are not physiologically injurious. It seems probable that the true explanation of the phenomenon is to be found in a combination of the two hypotheses: that on the one hand the curve representing the current variation would show moments of strong activity followed by longer intervals of very much smaller current, while, on the other hand, the inductance of current-elements on one another would cause a perceptible skin-effect and increase the resistance of every part of the circuit.

A WRITER in an esteemed scientific contemporary, signing himself "J. S.," points out, as we have pointed out more than once, that OHM's law of the resistance of a circuit is something more than a mere definition of electrical resistance. The expression $C = E/R$ represents, he says, a physical fact; namely, the fact that "the resistance of a circuit is constant as long as its physical conditions, such as temperature and linear dimensions, remained undisturbed." This we readily admit to be the proper intrepretation of the law; but we believe that, not only was OHM unable to demonstrate the truth of this, but quite failed as a necessity to grasp the fact that the law was a purely experimental result, the truth of which no one could have predicted. Such a generalisation as OHM's law which "J. S." propounds must rank with NEWTON's generalisations on gravitation, and can only be permitted when a large mass of experimental evidence from all sorts and conditions of conductors points in the direction of its validity. It is an induction which it would be highly dangerous to base upon experiments made only on a few feet of copper and iron wire of assorted gauges.

OUR selections from Mr. G. S. RAM's book on "The Incandescent Lamp and its Manufacture" are concluded this week. We should have made further extracts had time permitted, since the articles have, we believe, interested many of our readers who have no intention of concerning themselves with lamp-making, but who wish to know something of an important industry which has hitherto been kept strictly secret, and on which nothing has been written since Mr. J. SWINBURNE's series of articles in *The Electrician* in 1887. The book will be published early next month.

THE impudent announcement of the issue of new shares in the Medical Battery Company by HARNESS serves to show how a cunning impostor may flourish if he can elude the letter of the law. Having lost, or settled by payment of considerable sums, every law-suit in which endeavours have been made to expose his doings, he yet managed to keep out of Court all the mass of evidence which had been carefully collected. Actions for obtaining money under false pretences, for libel, or prosecutions by any medical association, are all beside the mark. We have more than once urged that a Treasury prosecution should be instituted, which should result in the stamping out of that which was characterised before Lord Chief Justice COLERIDGE as an "abominable system of imposture." A vigorous article in the *Pall Mall Gazette* of yesterday denounces HARNESS and his Company, and promises in future issues to publish some of the evidence to which we have alluded.

Cable Interruptions and Repairs.—There are no cable interruptions to record this week.

The Telephone in Scandinavia.—One of the longest telephonic communications in Europe was recently opened between Christiana and Stockholm. The distance between the two cities is about 250 miles.

The Institution of Electrical Engineers.—The annual dinner of the Institution of Electrical Engineers has been arranged for Wednesday, November 22nd, and will take place at the Freemasons' Tavern, Great Queen-street.

The Mashonaland Telegraph Lines.—Telegraphic communication between Cape Town, Forts Victoria, Charter and Salisbury, which was interrupted on Tuesday and Wednesday of this week, has been completely restored.

Telephonic Communication between Barry and Cardiff.—A subsidiary line is in course of construction, and will be completed shortly, between Cardiff and Barry, in order to provide facilities to cope with the rapidly increasing volume of telephonic business at the post office at Berry Dock.

Fire at Finsbury Technical College.—A fire was discovered on Wednesday evening in the chemical lecture room of this college. Some damage was done to the lecture table and flooring, but the fire was quickly extinguished by the fire brigade, who, of course, attributed it to the "electric light." The cause is unknown.

Telephonic Communication with Lightships.—Instructions have been given for the immediate laying of cables between the shore and the Kentish Knock and North Goodwin Sands Lightships for telephonic communication, so that the work may be done before the winter sets in. The cable to the North Sands is to be landed at Dumpton Gap, Ramsgate, and the cable for the Kentish Knock at Kingsgate Bay.

Kingston-on-Thames.—The new electric light station at Kingston-on-Thames will be opened by the Mayor to-morrow. The town hall and other municipal buildings have been fitted with glow lamps, and among the largest of the private consumers will be the Surrey County Council, who are having their new buildings wired. Street lighting will be effected by means of 36 arc lamps, rated at 1,000 c.p. each. The generating plant has been built by Messrs. Siemens Bros. and Co.

Personal.—We understand that Mr. Joseph A. Jeckell, late Works Manager of the International Okonite Company, has been appointed Electrical Engineer to the Borough of South Shields.——Mr. Hylton Spagnoletti is about to sever, or has already severed, his connection with the National Telephone Company, after eight years of successfully piloting the Swansea branch of the late Western Counties and South Wales Telephone Company. Messrs. J. B. Saunders and Co., of Cardiff, have secured Mr. Spagnoletti's services as their agent in Swansea and district for electric light installations and private telephone work.

Great Storm in America.—The storm which recently visited the United States swept over a wide area. It was felt from the Gulf of Mexico along the coast to Maine, and reached westward as far as Buffalo. Telegraph wires were thrown down, delaying the reports of the damage done. At Baltimore two electric light wires became crossed in the tower of the Brush Electric Light Works, setting fire to the tower. Pieces of blazing wood were blown to the rafters of the gaol near by, where five hundred and forty-four prisoners were confined, and the building was burned down. The prisoners were rescued with difficulty, one man being killed and twenty injured. The loss to the Electric Company amounts to two hundred thousand dollars, and the burning of the gaol entails a loss of fifty-five thousand dollars.

Train Lighting.—The Directors of the London, Brighton and South Coast Railway have given instructions for the equipment of ten more trains with the electric light. This will make a total of 40 trains so fitted. We understand that the superiority of this method of lighting is very marked, and affords much satisfaction to those working the traffic. Especially is the benefit felt in busy times and foggy weather, when under ordinary circumstances gas-lighted trains would have to be sent specially to the charging stations or put out of working altogether. It is estimated that at least 15 per cent. more work is got out of electrically-lighted trains than gas-lighted trains for the above-mentioned reasons. This simply, in the construction of say 100 trains, would mean a saving of something like £45,000 in first cost, *i.e.*, 85 electrically-lighted trains would do the work of 100 gas-lighted trains.

Canadian Electrical Association.—The third Convention of the Canadian Electrical Association was, says the *Canadian Electrical News*, in every way a success. The Papers were of a high order, and gave rise to interesting and valuable discussions. By means of Papers such as the one presented by Mr. McFarlane the Association will be the means of collecting much interesting data concerning the early history of electrical matters in Canada which might otherwise be lost, and which will form a valuable record in years to come. The Association was fortunate in having present at this Convention, not only members from all parts of Ontario and a good delegation from Quebec, but also representatives of the North-west Territories and British Columbia. Next year, when the Convention will be held in Montreal, it is hoped that Nova Scotia and New Brunswick will also be represented. The decision to have the next Convention in Montreal will no doubt tend to give the Association a more cosmopolitan character. The steady increase in membership is a gratifying sign of progress.

Fog Signalling by Electricity.—The Great Northern Railway Company have been extending, on their North London branches, the experiment of fog signalling by means of electricity. The method of working is very simple, and is the invention of an electrician in the employ of the Great Northern Railway Company. A wire is laid, by means of a pipe, from the signal-box to the various signals, at which points brushes, composed of copper wire, project some 4in. or 5in. above the side of the rail nearest the signal. To the foot-plate of the engine a similar brush is fixed, connecting with an indicator and bell on the engine. If the signal be at danger the two brushes coming in contact has the effect of ringing the bell and indicating to the driver, by means of a miniature signal fixed on his engine, that the line is not clear. The arrangement can be switched off in fine weather. The process, which is in working order at Wood Green, has proved so satisfactory that the Company, it is said, have decided to fit up the suburban lines, and eventually the whole of their system.

Extension of the Electric Lighting of Glasgow.—The station which the Corporation erected in Waterloo-street to meet the wants of the central area of the city was equipped at the outset with machinery which it was thought would suffice for several years at least. It consisted of seven Willans central-valve compound engines—two of 80 H.P., two of 150 H.P., and three of 250 H.P.—and an equal number of dynamos, two having an output of 400 amperes at 120 volts, two an output of 400 amperes at 230 volts, and three an output of 670 amperes at 230 volts. The applications for light for private premises have been so numerous that at present two new engines of about 850 I.H.P. each are being put down to light an equivalent of 14,000 8-c.p. incandescent lamps. Beyond this plant the station contains four dynamos for the arc lamps with which the streets are illuminated. The station was originally designed to supply 22,000 incandescent lamps. The new machinery, however, will increase the number to no fewer than 40,000. The current is used for the most part for lighting purposes, but in several cases it is being employed to drive motors and ventilating fans. The Municipal Buildings take the largest supply yet sent out, the lamps there being equivalent to 1,500 of 8 c.p. In the Post Office there are 1,000. The Theatre Royal has 1,160, the Clydesdale Bank 900, the Union Bank 744, and the Central Agency, Bothwell-street, 700. As matters are at present, the station cannot give any more light to private consumers, and in the meantime it has been decided not to consider any new applications. The station, in fact, has reached the limit of its load, the output on Friday being 4,340 amperes at 100 volts, which is equal to 13,000 8-c.p. lamps actually lighted.

ELECTROMAGNETIC THEORY.—LVI.

BY OLIVER HEAVISIDE.

(Continued from page 605.)

§ 215. We have now to consider in what way self-induction comes in to influence the transmission of waves along wires. The first step in this direction was made by Kirchhoff as long ago as 1858, but it is only in recent years that self-induction has become prominent as an active agent, and its real resultant effect worked out and understood. more or less. This effect is, on first acquaintance, a somewhat surprising and paradoxical one. Everyone knows the impeding effect of self-induction in apparatus. How, then, in the name of Faraday, can it be beneficial in a telegraph or telephone circuit, and make signals bigger and clearer? It will be convenient to make use of an analogy in the first place.

There is, in a great measure, a formal resemblance between the problem of a telephone circuit along which electromagnetic disturbances are being propagated, and the mechanical problem of the transverse motions of a stretched flexible cord. But to make the formal resemblance be also a practical resemblance, several little things have to be attended to, and reservations made. Now there are a great many mechanical problems concerning wave-motion subject to friction which make better analogies for the use of the mathematical inquirer; but the case of a flexible cord is more or less familiar to everyone, and is, up to a certain point, easily realisable.

The commonest knowledge of the transverse motions of a stretched cord is concerning its normal vibrations, the fundamental mode and its harmonics. But we do not want them in our analogy. For although we may have something similar with short waves, and especially Hertzian waves, it would not be easy to set up such a state of things on a telegraph circuit, which is usually so long as to prevent the assumption of normal modes by reflection at the ends. For the normal vibrations of a cord are complex affairs, depending not only upon propagation of motion along it, but also on the constraints to which it is terminally or intermediately subjected. We desire the propagational effect to show itself distinctly. But if we disturb a stationary stretched wire at one end, the pulses produced run to and fro too quickly for practical observation. Take, then, a long india-rubber cord, suspended from a height, as is sometimes done by lecturers. The speed of transmission of pulses may be made small enough to allow the disturbances to be conveniently watched. Then, if the cord hang vertically at rest to begin with, and its lower end be momentarily jerked, bringing it immediately back to its original position, a hump is generated, which runs along to the fixed end. It is not much changed in transit, and is reflected back, and re-reflected many times. But we only want to consider the passage of a hump one way. Properly speaking, then, we should have so long a cord that reflection is (by frictional loss) insignificant. Perhaps a very long cord laid upon a surface of ice would be more suitable for the purpose. But if the "fixed end" be movable transversely, and its motion be resisted by a force proportional to its velocity, their constant ratio may have such a value given to it (depending upon the mass and tension of the cord), that the arriving disturbances do not produce any reflected waves, but are absorbed by the terminal resistance. The cord then behaves as if it were infinitely long. This is theory, of course, but I dare say a sufficiently good practical imitation could be got by means of a terminal block sliding upon a wire with friction. An imperfect cancellation of the reflection is easily got.

Disregarding the slow change of type and the attenuation, so that there is undistorted propagation of a hump, or of a succession of humps making a train of waves going one way only, this case is analogous to the transmission of waves along a uniform circuit of no resistance. The two constants L and S in the electrical case are replaced by another two, viz., the density (linear, or mass divided by length) and tension of the cord. Thus, large permittance, that is, small elastance, means small tension, or a slack cord; and large inductance means a massive cord. If I said a "heavy" cord, it might be thought that its weight was concerned in the matter in question, but it is not, save as a disturbing factor. The transverse displacement of the cord may be compared with the transverse voltage in the electrical circuit. Other comparisons (theoretically better) may be made, but this is perhaps the most convenient if the motion of humps be actually watched.

Now to imitate the action of the resistance (assumed to be constant) of an electrical circuit, the transverse motion of the cord must be frictionally resisted, and the frictionality (or coefficient of friction) should be constant. That is, the frictional force should be proportional to the transverse velocity. The motion of the cord is frictionally resisted, both internally and externally. It is very unlikely that this should give rise to a constant frictionality, but there is a similarity insofar as the waves sent along the cord do attenuate and are distorted as they progress.

But the friction is not anything like enough in the case of a cord in air to imitate the submarine cable; besides that, the mass is too great, and likewise the tension. Even to copy telephonic waves going along very long copper wires of low resistance, we should increase the friction in the mechanical analogue if we desire to have an equal amount of attenuation in a wave length. The cord should, therefore, be in a viscous medium, and the viscous resistance to the cord's motion should be so great as to produce a marked attenuation during the transit of a hump, though it should not be so great as to prevent its distinct propagation as a hump, without great distortion of shape and spreading out. Under these circumstances we may exemplify low-resistance, long-distance, overland telephony, where the inductance is relatively large and the permittance relatively small.

But to imitate a submarine cable we should have a slack cord of small mass in a highly viscous medium. We can then send a hump only a little way along it as a hump, for it becomes greatly distorted and diffused. Consequently, if we compared the displacements at a great distance along the cord with those impressed upon it at the free end, we should find a state of things quite different from what occurs in the case of an india-rubber cord in air. The main features of the originated disturbances might be recognised, unless the attenuation were too great, but they would be out of all proportion. In particular, there is a tendency to obliterate small humps, or ripples, whilst the big ones persist. The propagation is of the sluggish kind, characteristic of diffusion, quite unlike that of purely elastic waves. If the slack cord could have no mass at all, we should then imitate a submarine cable wholly without inductance.

Under these circumstances we could convert the diffusive waves to something like elastic waves by giving mass to the cord. Without changing either its tension or the frictionality, we could, by a continuous increase of density, cause the nature of propagation to pass continuously from the sluggish, diffusive kind to the elastic kind with approximate preservation of form of waves. We might also do the same by increasing the tension and reducing the frictionality (like, by reducing the permittance and the resistance in an electrical circuit, bringing the inductance into importance). But these are not immediately in question. By increasing the mass, or equivalently the inertia of the cord, we impart momentum to the waves, which allows them to be carried forward, in spite of the little tension, against the resistance of the surrounding medium.

So it is in the electrical case. By increasing the inductance we impart momentum to the waves, and that carries them on. This statement is independent of the particular mechanical analogy that may be employed for illustration. It is, probably, representative of the actual dynamics of the matter, associating L with inertia, and LC with momentum. The soundness of this dynamical explanation (made by me some years since in asserting and proving the fact concerned) was endorsed by Lord Kelvin. And I am proud to add, for the benefit of those who may excuse themselves from understanding me by the plea that I am a Schopenhauer (!), that Lord Kelvin expressed his appreciation of the very practical way in which I had reduced my theory to practice.

Many other dynamical arrangements might be alluded to, exemplifying the power of inertial momentum to overcome

Digitized by Google

frictional resistance, but it is not easy to get a good one exhibiting elastic waves plainly.

To illustrate the nature, and to emphasise the possible magnitude of the effect, suppose we have the power of continuously increasing the inductance of an Atlantic cable from a small quantity up to a very large one, without altering its resistance or permittance, and without introducing any other actions than those to be controlled by resistance, permittance, and inductance. Starting with L = 0, and making, say, 1,000 waves per second at one end, there will be 1,000 waves per second of workable magnitude only in a small part of the cable near the sending end; the amplitude will attenuate to insignificance, not exactly in the shore-end, but before 100 miles is traversed. But let waves of the same size (which will need greater battery power to produce) be kept up at the sending end, whilst L is continuously increased all along the cable. The region of practical waves will continuously extend itself right through the cable, by a partial conversion to elastic waves, with little attenuation in transit. With very big inductance the waves would reach the distant end nearly in full size. Even then they could be doubled in size by the reflection, though there would be no useful purpose served by that. The amount of inductance required, however, to produce these results would be out of all reason. Nevertheless, the illustration serves its purpose in showing the action of self-induction, which is, as before stated, wholly beneficial, as it increases the amplitude and lessens the distortion. Some remarks on increasing inductance will come later.

§ 216. In the meantime, some few remarks on self-induction combined with leakage should come in here. Self-induction came in with the telephone. That was, originally, a mere house-to-house affair. At any rate, lines were only a few miles long. So condenser action was out of practical question then. On the other hand, the frequency of the currents concerned is very great, and that makes inertia important. So the theory of telephones is a magnetic affair when the lines are short enough, just as if they were lines in a laboratory.

But the telephone soon got beyond that, and it became necessary, with the use of longer and longer lines and underground lines, to examine the influence of their permittance in conjunction with their inductance. In hardly any case of telephony can we ignore the self-induction, and take the permittance alone. The resistance would need to be so large that the lines would be wholly unsuitable for telephony, except for mere local lines. So permittance and inductance usually go together in considering telephony, and if one of them is ignorable it is the permittance rather than the inductance.

Following the telephone came exchanges. But there was an exchange before telephones. My brother, Mr. A. W. Heaviside, had an intercommunication exchange at Newcastle, using alphabetical indicators, whereof the manipulation resembled that of the hurdy-gurdy. These were beautiful instruments mechanically; but, of course, the telephone soon stopped their manufacture. The exchange referred to was then turned into a telephone exchange. Now, in certain cases it was needed to have many instruments in one circuit, with local intercommunication; a sort of family arrangement, so to speak; for example, a number of coal pits and colliery offices belonging to one firm. The custom was to set all the intermediates in sequence (otherwise, but perhaps not so well, called in series) in the circuit. Why was this done? Simply because they knew no better. It was the custom to do so in the telegraphs generally, being an obvious arrangement—not so much in England, though, as elsewhere. But when this was done with telephones, or with call-instruments replacing them, it was found that the intermediates had a very deleterious influence, which very soon set a limit to the admissible number of intermediates on a circuit and to the length of the circuit, especially when underground wires were included. My brother, who took up the telephone with ardour from the first (making the first one made in England, I believe), found by experiment that it was quite unnecessary to put the instruments in sequence according to old practice, and that an immense improvement was made by taking them out of the circuit, and putting them across it, as shunts or bridges. Like lamps in parallel, in fact. It seems very easy and obvious now. But it is not so easy to conceive the state of mind of old stagers. Anyhow, the proposition to put the instruments in bridge was pooh-poohed at first, not being understood. As, however, it was demonstrably a wonderful improvement it was adopted, first at Newcastle, and then elsewhere, and became known as the Bridge System.

When this system was brought to my knowledge, and I was asked for theoretical explanation, it presented itself in a double aspect. First of all, there was the complete removal from the circuit of intermediate impedance in big lumps. This was manifestly the main reason of the increase in working distance possible, and why a far greater number of intermediates could be put on. For they were not put in the circuit, but on it, so to speak.

The other aspect of the matter was this. Considering that the bridge system consists electrically of a circuit with a number of leaks on it, and bearing in mind my old investigations concerning leaks, I inquired whether the intermediates were not actually beneficial to through communication, independently of the previous effect. Was not the articulation better, not merely than if the intermediates were in series in the circuit, but better than if the shunts or bridges were removed altogether, leaving insulation? My brother's answer was Yes, certainly, in certain cases, but doubtful in others. It appeared, however, to be only a minor effect, of not much importance compared with the major one. Besides, the bridges caused a weakening of the intensity of the speech received when many bridges were passed. To prevent this weakening becoming inconveniently great, the intermediate call-instruments in bridge were purposely made to have considerable resistance and inductance, far more than would be needed or desirable for their natural use. This tended to prevent the currents passing along the line from entering the shunts, and especially so as regards the currents of high frequency, and allowed them to be transmitted in greater magnitude.

It will be observed here that the expediting effect of leakage considered before (§§ 213, 214) is merely incidental, and is, in fact, partly destroyed by the large impedance of the bridges, in order to mitigate the attenuative evil. The shunts are inductive shunts, intentionally very much inductive. Now, my proposed leaks (§ 214) for submarine cables were non-inductive, and intentionally so, though it may be remarked that it would make very little difference with the slow signalling of Atlantic cables if they were inductive. On the other hand, a recent proposal of Prof. Silvanus Thompson is to use inductive shunts on cables. The arrangement is electrically as in the bridge system, but the object is different. This point will be returned to.

The investigation of this bridge system of telephony suggested to me the distortionless circuit, as I have before acknowledged ("Electrical Papers," Vol. II., p. 402). It may be of interest to state how it came about, since it is not presented to one by the above-described experiences with the bridge system. The question was, What was the effect of a bridge, or of a succession of bridges, when the self-induction of the line was not negligible? Now the influence of the bridges can be very readily stated for steady currents, of course. There is no difficulty, either, in finding the full formulæ required to express the voltage and current and their variations in any part of the system when the inductance and permittance are operative, as well as a set of leaks, when one knows how to do it. But the general formulæ thus obtained are altogether too complicated to be readily interpretable. I was, therefore, led to examine the effect produced by a leak on a wave passing it of the elastic type. This implies that the resistance of the line is sufficiently low for waves of the frequency concerned to retain that type approximately. (L*n* should be greater than R.) Now this was comparatively an easy problem, and the result was to show that a leak (or conductance in bridge) had the opposite effect on a wave passing it along the line to that of a resistance inserted in the circuit at the same place, in this sense:—A resistance in the circuit reflects the charge positively and the current negatively, or increases the charge and reduces the current behind the resistance. On the other hand, a leak reflects the current positively and the charge negatively, or increases the current and reduces the charge behind the leak. (*See* also §§ 197, 209.) A resistance and a leak

Digitized by Google

together at the same place therefore tend to counteract one another in producing a reflected wave, leaving only an attenuating effect on the transmitted wave. This led to the distortionless circuit. For although the compensation of the resistance in the circuit and the conductance across it is imperfect when they are finite, it becomes perfect when they are infinitely small. They may then be a part of the circuit itself, namely, the resistance a part of the resistance of the line, and the conductance a part of the leakage. We now have perfect compensation with this one, or any number of successive resistances and leaks of the same kind, provided their ratio is properly chosen. This occurs when R and K, the resistance and conductance per unit length of circuit, of the line and of the leakage respectively, are taken in the same ratio as the two other constants, L and S. Or, when $L/R = S/K$, indicating equality of the electric and magnetic time-constants. There is now an undistorted transmission of any kind of signals. And since every circuit has R, L, and S, it follows that it can be made distortionless by the addition of leakage alone of a certain amount, or distortionless to the extent permitted by the approximate constancy of R, L, and S. (*See* "Electrical Papers," Vol. II., pp. 119 to 168, for detailed theory of the distortionless circuit.)

In § 213 we saw that even in the electrostatic theory leakage would allow us to signal as fast as we liked provided we could do it with an infinitesimal current. This was not because the circuit was made distortionless, but on account of the infinitely rapid charge and discharge. Now the inclusion of the influence of self-induction shows that we can do the same with a finite leakage conductance, and have finite distortionless signals, due to waves of the purely elastic type. Given R and S then, if L should be so small that the introduction of K of the proper amount to reach the distortionless condition should produce unreasonable attenuation, then one way of curing this would be to increase L. For then a smaller amount of leakage will serve. The bigger L, the smaller need K be, and when it is very big, then very little K is needed. This brings us round to the case at the end of § 215, where we had elastic waves with little attenuation on an Atlantic cable got without any leakage, and since we see now that very little leakage is needed to bring about the distortionless condition, we conclude that it is approximately distortionless without the leakage.

(To be continued.)

ON THE PIEZO-ELECTRIC PROPERTY OF QUARTZ.*

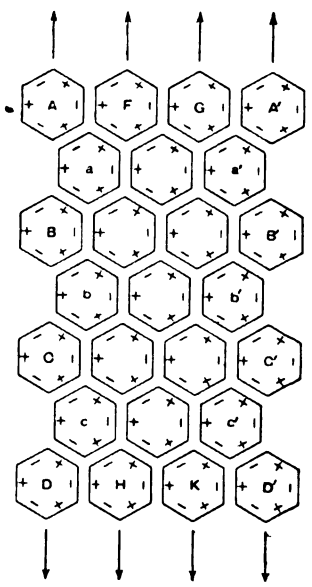
BY LORD KELVIN.

The sides of the hexagonal constituent molecules (as we shall see presently in considering the electric effects of changes in their relative positions) must make angles of 30deg. and 90deg. with the sides of the hexagon of the natural crystal. The annexed diagram shows, in section perpendicular to what is commonly called "the axis of the crystal," a rectangular group of 25 molecules, with its length perpendicular to a pair of parallel sides of this hexagon; and with, for its thickness, rows of alternately four molecules and three molecules. The molecules marked A *a* B *b* C *c* D, A′ *a* B′ *b*′ C′ *c*′ D′ are in the two sides of the thin plate of the Curies' experiment; and the breadth of the plate is made up in my model by building up layer over layer each similar to the one shown in the diagram, all similarly oriented, of course. The zinc and copper faces of the molecules are marked + and − respectively. The air-spaces between them are exactly equal in the diagram, which is intended to represent the undisturbed configuration.

Suppose, first, the molecules to have each of them equal quantities of positive and negative electricity on its whole surface: which would be the case if they were given in this condition, and brought together from infinite distances to the positions shown in the diagram, each kept perfectly insulated. Let them be all now metallically connected (by infinitely fine wire, understood). The total quantity of electricity on each will remain zero, because every interior molecule experiences equal positive and negative induction from neighbours; and, except for an infinitesimal irregularity due to the four corners, A, D, A′, D′, which we neglect, each individual molecule in the end rows A F G A′, and D H K D′ experiences equal positive and negative inductions from neighbours; and each pair of molecules, *a*B, *b*C, *a*′B′, *b*′C′, in the side rows experiences equal sums of positive and of negative inductions from neighbours. Thus, for example, the effect on B *b*, of the connecting, is merely to cause a quantity of positive electricity to flow from *b* to B, because two faces of B gain positive and one gains negative, while two faces of *b* gain positive and three gain negative.

Let, now, all molecules in the side rows A *a* B *b* C *c* D be kept in metallic connection with one another, and so also all in the other side, A′ *a*′ B′ *b*′ C′ *c*′ D′; but let all the other connections be annulled, and the molecules left insulated. This corresponds to the Curies' silvering of the two sides of their plate.

Under these conditions, let such forces be applied to the boundary molecules as shall produce the simple elongation of the whole configuration indicated by the arrows. This will leave the air-spaces between faces parallel to the lines of elongation unchanged, and will increase all the others, each by



the same difference. The electrical result will be the release of approximately equal quantities of electricity, whether positive or negative, from all of the opposed faces not parallel to the lines of elongation. Each interior molecule will lose, very approximately equal quantities of positive electricity from two of its faces, and of negative from two others. Each of the molecules in the end rows, F G. . . , H K. . . , will lose positive electricity from one face and negative from one other face.

But each projecting molecule, such as B, on one side will lose positive electricity from two inward faces, while each non-projecting molecule, *b*, loses positive electricity from two inner faces and negative from other two. Thus, of the eight inner faces of B and *b*, there is neither gain nor loss from two, there are equal losses and gains from four, and there are losses of positive electricity from two. The positive electricity thus freed from the inward faces of the projecting molecules A B C D in the side A *a* B *b* C *c* D settles itself on the bare faces to the left; similarly, negative electricity, freed from the inward faces of the other side, A′ *a*′ B′. . . becomes deposited on the bare faces to the right, which is the Curies' result.

The quantities of electricity thus developed are calculated in a moment, if we suppose the thicknesses of the air-spaces to be small in comparison with the diameters of the molecules. So also is the electrostatic inductive capacity of the assemblage; and thence the difference of electric potential between the two silvered sides, if none of the developed electricity is drawn off

* Addendum to a Pape read in Section A of the British Association.

A POTENTIOMETER METHOD OF MEASURING THE ELECTROMOTIVE FORCE OF TRANSFORMERS.

BY BERNARD P. SCATTERGOOD, B.A. OXON.

(*Concluded from page 645.*)

Of course, it is not necessary in practice to make use of the graphic method at all; the balancing point is easily found by a simple calculation. If d_1 d_2 are two nearly equal deflections on opposite sides of it, and V_1 V_2 the standard voltages at which these deflections respectively occur, the balancing point V_0 is, by the principle of similar triangles, given at once by the formula

$$V_0 = V_1 + \frac{d_1}{d_1 + d_2}(V_2 - V_1).$$

Or from the two nearly equal deflections the E.M.F. required may be found, perhaps more easily, and with sufficient accuracy, by the following rule, the *rationale* of which will be easily understood:—Add to the sum of the two standard voltages

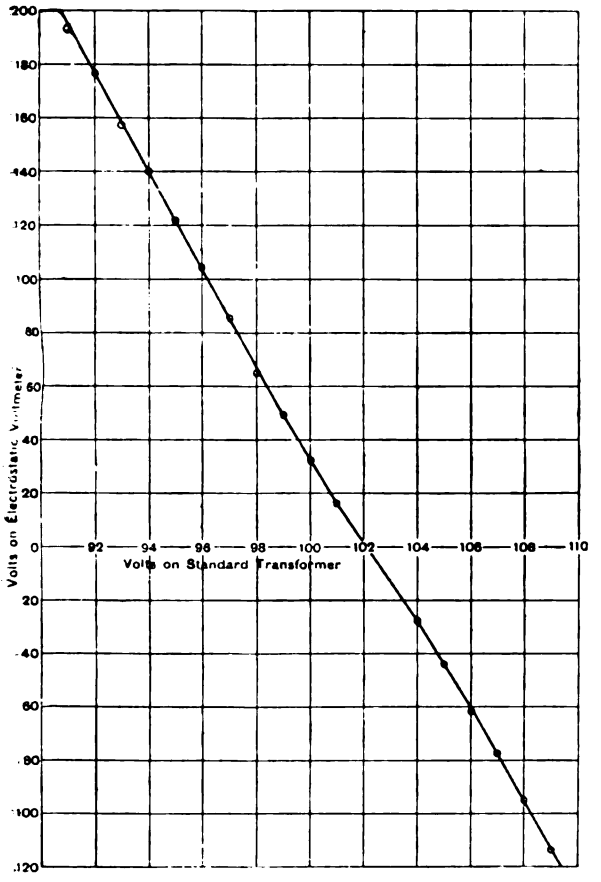

FIG. 3.

the difference of the two deflections divided by the (actual) conversion ratio of the auxiliary transformer used; half the sum will be the E.M.F. required. Or, using the preceding notation

$$V_0 = \tfrac{1}{2}(V_1 + V_2 + n(d_1 - d_2)),$$

n being the conversion ratio.

An example may make this clearer. Taking at random two readings from Table I. we see that one auxiliary transformer gives, with 95 volts on the standard, a deflection of 135, and with 109 volts a deflection of 130. The E.M.F. of the transformer which is being tested is therefore

$$\tfrac{1}{2}\left(95 + 109 + \frac{135 - 130}{20}\right),$$

or 102·13 volts, which is sufficiently near to the true voltage namely 102·15.

When a batch of transformers of the same type is to be tested, it will be found quicker, and quite sufficiently accurate, to take two readings, as just indicated, of the first one tested, and from them to determine the slope of the line, *i.e.*, the "virtual conversion ratio" of the auxiliary. When this value has been found it can be applied, in the case of the remainder, to calculate from a single deflection, the E.M.F. acting in the circuit; and hence, the standard voltage being known, the E.M.F. required is at once found. For instance, the virtual conversion ratio being found to be 1 to 19, if a standard voltage of 93 gives a deflection of 127, the secondary E.M.F. will be

$$93 + \frac{127}{19}, \text{ or } 99{\cdot}68 \text{ volts.}$$

It may be pointed out that an error in the calibration of the voltmeter used will make practically no difference in the accuracy of the results obtained, as the only effect will be to alter the slope of the line joining the two observed points; the line will still cut the horizontal axis at the balancing point. An instance of this has just occured in my own experiments. Owing to an accident the multicellular voltmeter which was being used indicated between 30 and 40 per cent. low; but the voltage of a transformer which it was used to measure, agreed, to within the fiftieth of a volt, with the result obtained when the voltmeter was reading correctly.

As to the degree of accuracy obtainable, this is limited (assuming the standard voltage to be exactly known) solely by the conversion ratio of the auxiliary transformer used. With a steady primary voltage the voltmeter can easily be read, supposing the deflection to be at the best part of the scale (a condition which can always be attained), to a quarter of a volt; this, with a step-up transformer of ratio as low as 1 to 20, means a possible error of only one-eightieth of a volt in the estimation of the E.M.F. acting in the circuit; that is to say, if the E.M.F. of the standard is known exactly, that of a transformer giving about 100 volts can be measured with an accuracy of one part in eight thousand. This is, of course, a precision which is quite unnecessary in practice; but the great advantage of the method is the possibility which it holds out of obtaining rapid and sufficiently accurate measurements under conditions which, as before pointed out, would ordinarily make such measurements impossible.

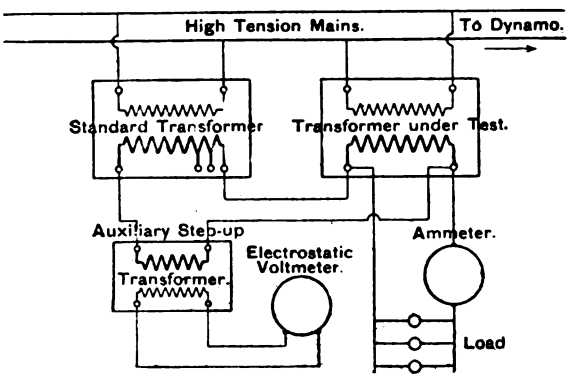

FIG. 4.

For instance, suppose, as an extreme case, the primary voltage to vary during the test between the normal and 10 per cent. higher than normal. The voltmeter readings will of course be unsteady, and it may be impossible to get a reading to be relied upon as being accurate within five volts; yet even this only means an error of one quarter of a volt in the E.M.F. of the transformer which is being measured. If an attempt were made to measure the secondary voltage directly the error would, of course, be five volts. Or, again, suppose the primary voltage to be steady, but, through an error in the calibration of the high-tension voltmeter, to be actually 10 per cent. higher than it is believed to be, say, 2,200 instead of 2,000. The secondary voltages of both standard and transformer under test are now each of them 10 per cent. high, and this is also the case with their difference, and, therefore, with the voltmeter deflection. But if another nearly equal deflection be taken on the other side of the balancing point, this will also be 10 per cent. high; hence the balancing point itself, as determined in the manner shown in Fig. 3 will remain

Digitized by Google

unaltered, being the same as when the primary voltage is normal.

It will be seen from the above instances how extremely elastic this method of testing is; with primary voltage unsteady, or wrongly estimated, or both, and with an incorrect voltmeter, it is still possible to get measurements which are quite sufficiently accurate for all practical purposes.

An obvious modification is to use, instead of the step-up transformer and voltmeter, an electro-dynamometer of fairly high resistance. I have obtained good results with a Siemens instrument which has a constant of 0·02 and a resistance of about 12½ ohms. This method is not so sensitive as the one just described, and has the disadvantage that the readings are affected to a much greater extent by the frequency of the alternations, and therefore by variations of dynamo speed; but it is simpler, and will often be found more convenient, especially where great accuracy is not desired.

After the "potentiometer" method had been successfully applied to the measurement of open circuit E.M.F., it became of interest to see whether that of a loaded transformer could not be determined in the same way. The results were quite satisfactory, and developed a method of testing by which not only secondary E.M.F., but lag of primary current behind primary E.M.F. and therefore the power factor of a transformer at different loads, can readily be measured.

The connections in this test are shown in Fig. 4, and are, as will be seen, altogether similar to those in the last case, except that a load of lamps, or a non-inductive resistance, is placed across the secondary terminals of the transformer to be tested, with an ammeter in circuit to measure the current.

The following table gives readings taken with the transformer previously tested, working on a non-inductive wire resistance.

Table II.—*Showing observed Voltmeter Deflections at Different Standard Voltages, with one, two, three and four Auxiliary Transformers, at a Load of 15·4 amperes (No. 1,669).*

Voltage of standard.	Voltmeter deflections.			
	Auxiliary, one transformer.	Auxiliary, two transformers. (Fig. 4, B.)	Auxiliary, three transformers.	Auxiliary, four transformers. (Fig. 4, A).
90	196·5	189·0	182·0	179·0
91	177·5	171·0	165·0	161·5
92	159·5	154·0	148·5	144·0

104	112·5	108·25	104·0	101·0
105	128·0	123·0	118·0	116·0
106	146·5	140·0	134·0	129·5
107	163·0	156·0	150·0	146·0
108	179·5	173·0	166·0	162·0
109	198·0	190·0	182·0	179·0
110	218·5	211·0	203·0	196·0

The current was kept throughout as nearly as possible constant at 15·4 amperes. The same transformers were used for the upward conversion as in the previous case, and, as before, were used in four combinations, one singly, and two, three, and four in parallel.

It will be seen at once that in this case the effective E.M.F. in the circuit, as measured by the voltmeter deflection, never becomes zero. It falls to a minimum, higher or lower according to the auxiliary transformer used, and then rises again. Two sets of readings have, as before, been plotted on squared paper (Fig. 5, A and B), and along with them has been plotted a third, C, which is the curve corresponding to an auxiliary transformer of infinite impedance, and which is actually a hyperbola. The way in which the points of this curve have been derived will be explained shortly. On the same diagram has been plotted part of the curve corresponding to a load of about seven amperes, and also, for the sake of comparison, the (corrected) no-load curve of the same transformer. It will be noticed that the axes of the new curves are shifted to the left with respect to that of the no-load curves; that is, the minimun deflection occurs at a lower standard voltage than the minimum (zero) reading in the case of the unloaded transformer.

Now it is clear that at some point between 90 and 110 volts on the standard, the E.M.F. of the transformer which is being measured must be equal to that of the standard. Why, then,

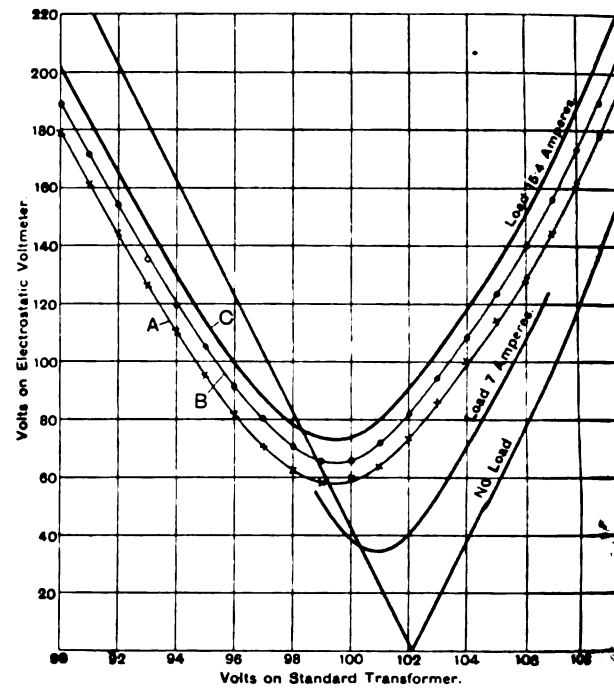

Fig. 5.—E.M.F. Curves of a 2-H.P. Lowrie-Hall Transformer (No. 1,669). A, Auxiliary Four 2-H.P. Transformers in Parallel; B, Auxiliary Two 2-H.P. Transformers in Parallel; C, Theoretical Curve.

do we not get a balance—that is, zero deflection—at this point? The answer is to be found in the phase difference of the two opposing electromotive forces. In fact, we know that as the load on the secondary of a transformer is increased the phase of the secondary E.M.F. is slightly accelerated with respect to that of the impressed primary E.M.F. (*vide* "Fleming," Vol. II., p. 454); and that instead of being exactly opposed to the latter, as in the case of an unloaded transformer, its position will be slightly in advance of this, to an extent which depends upon the load. Representing this state of things by a diagram (Fig. 6), if we

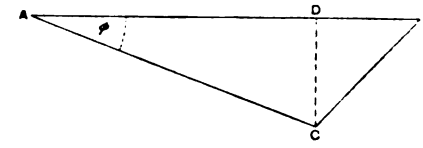

Fig. 6.

call the E.M.F. of the standard A B, that of the transformer under test will be represented in direction and magnitude by such a line as C A, inclined to A B at an angle ϕ. (In the unloaded transformer C A and A B are coincident, or $\phi = 0$.) The third side, B C, of the triangle represents the resultant E.M.F. which is impressed at the terminals of the auxiliary, and the deflection on the voltmeter is therefore proportional to this line

Now the secondary E.M.F. of the transformer under test and its phase are, for a given load, both of them constant quantities; that is to say, in the figure C A and ϕ are both fixed. The length of the line A B, however (representing the standard voltage) is variable; and it is easy to see that as the point B travels in the figure from right to left (that is, as the standard voltage decreases), the line B C grows shorter, reaching a minimum when B has arrived at a point, D, such that

Digitized by Google

B C is perpendicular to A B; and then increasing again according to the same law as that of its decrease. In other words, the effective E.M.F. in the circuit, as measured by the voltmeter deflection, falls until it is in quadrature with the standard voltage, and then rises again. Further, we see from the figure that when the minimum is reached, since A C has now become the hypotenuse of a right-angled triangle, A D C, the E.M.F. of the transformer under test is equal to the square root of the sum of the squares of the resultant E.M.F. (known from the voltmeter deflection) and of the standard voltage at the point where the minimum occurs.

Putting B C = y, B D = x, and D C = a, we have at once

$$y^2 - x^2 = a^2,$$

which is seen to be the equation of a hyperbola of eccentricity $\sqrt{2}$.

In the curves of Fig. 5 I have plotted on the vertical scale, not the effective electromotive forces B C, but voltmeter deflections (*i.e.*, B C divided by the ratio of conversion, $\frac{1}{20}$); and these distances again are all reduced in the ratio of 10 to 1. The effect of these two alterations is to change the eccentricity of the hyperbola from $\sqrt{2}$ to $\frac{\sqrt{5}}{2}$; for the equation of the curve now becomes

$$\frac{10^2}{20^2}\,y^2 = x^2 + \frac{a^2}{20^2};$$

or,

$$\frac{y^2}{4} = x^2 + \frac{a^2}{400};$$

or,

$$\frac{y^2}{\frac{a^2}{100}} - \frac{x^2}{\frac{a^2}{400}} = 1;$$

therefore, if e be the eccentricity,

$$e^2 - 1 = \frac{100}{400}, \text{ or } e = \frac{\sqrt{5}}{2}.$$

The hyperbola marked C in Fig. 4 was calculated in the following way:—The standard voltage at which the minimum observed readings occur was determined by careful measurements on the curves A and B, and was found to be 99·35 volts; the vertical through this point was taken as the axis of the hyperbola. From the four observed minima the minimum of the corrected curve (the quantity here called a) was found by direct proportion; and finally, the deflections y, corresponding to different values of the standard voltage x, were calculated from the equation,

$$y^2 = 4x^2 + \frac{a^2}{100},$$

and plotted about a vertical axis passing through the point of minimum deflection.* As regards the permissibility of determining the corrected minimum by extrapolation in direct proportion from the observed minima, it may be said that experiment shows that this would not be allowable in the case of transformers having a large magnetic leakage, as the minimum thus calculated would be too low; but so far as the determination of the secondary E.M.F. of the transformer is concerned, a considerable error in the estimation of this minimum makes but little difference in the result.

As an example of the order of the error which might be made, we may calculate from the curve C in Fig. 4 the E.M.F. of our transformer at a load of 15·4 amperes. The corrected minimum deflection is 73, therefore the minimum resultant E.M.F. in the circuit is $\frac{73}{20}$, or 3·65 volts, occurring at a standard voltage of 99·35; hence the required E.M.F. is $\sqrt{(99{\cdot}35)^2 + (3{\cdot}65)^2} = 99{\cdot}42$ volts, which agrees closely with the result obtained by a direct measurement in the ordinary way.

If the minimum were taken at 60 (the actual minimum with one auxiliary transformer) instead of 73, the E.M.F. would work out to 99·39 volts. Finally, to take an extreme case, let the minimum be taken as zero; the E.M.F. would then be simply that of the standard, or 99·35 volts; differing by only 7 parts in 10,000 from that calculated from the corrected curve. It would therefore in most cases be found sufficiently accurate to take, as the E.M.F. required, the voltage of the standard at the point where the minimum occurs.

It is not necessary to plot the whole curve in order to find the point of minimum deflection. Three observations are sufficient to determine the point with sufficient approximation to accuracy. One deflection is observed on one side of the minimum, and as far away from it as the adjustment of the standard voltage will allow, and two others on the other side of the minimum, such that the deflection previously obtained lies between them in numerical value. The two latter deflections should be taken with a difference of only one volt on the secondary of the standard. Then if d_1 d_2 d_3 are the three deflections (d_3 being greater than d_2) and V_1 V_2 V_3 the corresponding standard voltages, it can easily be verified that approximately

$$V_0 = \tfrac{1}{2}\left(V_1 + V_2 + \frac{d_1 - d_2}{d_3 - d_2}\,(V_3 - V_2)\right).$$

Furthermore we can calculate the angle ϕ by which the secondary E.M.F. has been advanced from its original position with respect to the primary E.M.F. For in the triangle of electromotive forces we have

$$\tan\phi = \frac{\text{minimum resultant E.M.F.}}{\text{standard voltage at which minimum occurs}};$$

or in the case taken,

$$\tan\phi = \frac{3{\cdot}65}{99{\cdot}35} = 0{\cdot}0367, \text{ or } \phi = 2^\circ\,6',$$

and the supplement of this angle, 177° 54′, is the phase difference between the primary and secondary E.M.F.

But we know that at full load, and indeed at loads considerably less than this, the secondary E.M.F. is in exactly opposite phase to the primary current. Hence the angle between the primary E.M.F. and the primary current is 2° 6′, and the cosine of this angle is the power factor at this particular load. Now the cosine of 2° 6′ is 0·994, or practically unity, which is in agreement with the result of recent experiment.

The application of this "potentiometer" method of testing transformers to the investigation of the phase-relations of primary and secondary electromotive forces seemed to me to present features both of interest and utility sufficient to warrant me in presenting a brief description of it to the readers of this paper. It appears also to be capable of considerable further development, of which, and of other practical applications which have suggested themselves to me, I hope to say more on a future occasion.

* It may be pointed out that the asymptotes of this hyperbola are inclined to the horizontal axis at an angle tan $^{-1}\frac{1}{n}$, where n is the conversion ratio of the auxiliary transformer used. They are, in fact, simply the "no-load curve" shifted to the left.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

FRIDAY, October 27th.

PHYSICAL SOCIETY.

5 p.m. (1) Mr. C. E. Rimington: "On Air-Core Transformers." (2) Two experiments. Mr. W. B. Croft, M.A.: "On the Rings and Brushes in Crystals, and Electrical Radiation in Copper Filings."

WEDNESDAY, October 25th.

INSTITUTION OF MECHANICAL ENGINEERS
(At the Institution of Civil Engineers).

7:30 p.m. Mr. Benjamin A. Dobson, of Bolton: "On the Artificial Lighting of Workshops."

The Electric Light at the Royal Exchange.—The Royal Exchange is at last to be lighted by electricity, and merchants who go on 'Change will now no longer be compelled—as has happened on several occasions—to suspend business on foggy days owing to insufficiency of light. Correspondence on the subject has recently taken place between Mr. S. Montagu, M.P., and Mr. J. Watney, the clerk of the Gresham Committee (who manage the property within which the Exchange lies). The result is that the Committee have now decided to have the quadrangle lighted electrically as soon as possible, and a letter to this effect has been addressed by the Clerk of the Committee to Mr. Montagu. The Committee hope to complete the work before Christmas.

Mr. JOSEPH WILSON SWAN.

AMBIGUITY IN SCIENCE.

Ambiguity in science means false science. Properly speaking, we should say ambiguity mixed with science; for, ambiguous science, or ambiguity in the nature of science, involves a contradiction in terms. Still, as pure gold may be admixed with earthy matter, so may pure science be muddled up with a great deal that is non-science and often nonsense. The essence of all exact knowledge, or science, is (we have it on the authority of SOCRATES) definition; and the essence of a perfect definition is that it shall be explicit, free from ambiguity, that its terms shall verbally cover the entire extent of the ideas which it is to convey, but that they shall not pass the bounds of that extent by one jot or tittle. Such is the ideal definition; it is a thing about which there cannot be the least rational quibble or ground of dispute. Unfortunately this high ideal is far from being attained in many of our departments of science. It is the natural consequence of the progress of the human race, intellectually, from a state of complete ignorance through widening stages of incomplete knowledge, that there have arisen on the field of human knowledge isolated patches of wisdom, separated by dark tracts of ignorance, insulated oases on an arid desert. These several separate regions of knowledge have been long in revealing any trace of their true connection to the whole, or of their relation to one another; so that the processes of thought, and the definition of thought, in each has proceeded almost, if not quite, independently for many generations. It would be scarcely possible for such to be the case without the introduction of a great deal of ambiguity and confusion whenever two or more of these isolated patches of knowledge become blended into one united area. Confusion arises on many grounds; we may pause to notice two in particular. The one is the adoption of precisely

Digitized by Google

the same term for two or even more totally different areas of thought; the other is the converse, the use of several different phrases to cover identically the same area of thought. Instances of the latter are abundant, but of less importance than the former. Electrical engineers do not, for example, label the currents in a conductor with names indicative only of their sources, unless, indeed, there is an inherent difference between the currents themselves; while recognised medical authorities talk glibly of their "cathodic currents," and "anodic currents" their faradisation, and auto-conduction. The use of the same term to convey several distinct ideas is more common, and often of more serious consequences. A simple illustration occurs in the case of the over-loaded word "solid." The geometrician thinks of three axes of space, the physicist calls up the contrast of "fluid," the engineer contrasts a "hollow," other people have other ideas; all conjured up by the one word "solid." Another example is the unhappy word "polarisation"; while, in connection with the use of physico-mathematical symbols, nothing could be more remarkable than the use of the symbol μ in optics and in electromagnetism, and the result arising from the union of those two sciences.

But the unavoidable ambiguities which arise when two previously isolated systems or branches of science are blended are tolerable as compared with the wanton employment of standard and universally recognised terms to cover the nakedness of parts on the border of a quite unrelated science, as has been perpetrated recently by a leader of biological science. Whatever may be the views adopted as to the relationship of life to physical force, there can be no dispute that physiology and its allied sciences, of histology and morphology, are in close touch with physical and chemical sciences; and that nothing can be gained, but rather that a great deal will be lost, by importing such explicit phrases as energy from the latter into the former sciences, for the purpose of veiling the ignorance of the latter with a hall-marked name. In his Presidential Address before the British Association, Dr. Burdon-Sanderson unblushingly fixed the word *specific* before the word *energy*, without any intention whatever of specifying either quantity or quality of energy in either quality or quantity of matter, but for the sole purpose of applying this hybrid, meaningless phrase, "specific energy," to the vital functions of protoplasmic cells. "The term energy," writes Dr. Lodge in *Nature*, "is a physical one given us by Thomas Young, and it has been fought for by us through a great part of this century. It will be wanted seriously by physiologists before long, in its proper sense, and it will be a thousand pities if they misuse it." We would even go further, and aver that the term energy is wanted seriously by physiologists even now, in its proper sense, and is used by them. For in terms of what other quantity than physical energy can they estimate the katabolism or the anabolism of a living cell? Certainly not in terms of the amount of matter, for that measurement would often be the very inverse; nor, indeed, in terms of the chemical constituents of the protoplasmic cell (even if it could be estimated), for the relationship is uncertain and by no means stable. No; physiologists and all students of nature require the term energy in its established usage; and it is sheer vandalism to ruthlessly force it to signify something else, especially something which is beyond the border of inanimate physical agency. Physico-chemical, or even mechanical, "explanations" of life may be indulged in, if they assist in formulating ideas; but let the new ideas be labelled with new names to suit them, and not with those torn from their fastenings to other sciences.

Physicists should jealously guard the term energy, as Dr. Lodge thus does. It is daily used in a loose sense by engineers, and electrical engineers especially are liable to talk of the transmission of energy when they mean the transmission of power. Engines, dynamos, cables, and motors are all designed with reference to power; secondary batteries and coal bunkers alone are considered with reference to energy. A definition is a serious affair, and ideal definitions are perhaps rare. The definition of energy as "the capacity for doing work" ought to suffice for most people, but metaphysicians are inclined to complain that "energy" has been ear-marked by modern writers, and that the ἐνέργεια of Aristotle is the same now as it was two thousand years ago. A young Oxford philosopher, against whose attacks we were recently defending the accurate use of the word energy, and who was somewhat interested in learning that by an expenditure of work energy could be stored, argued that, according to our definition, the sharpness of a knife is a form of potential energy, stored up by work done on a grindstone, and giving the knife a greater capacity for doing work! To such shocking results are we led by Ambiguity in Science.

THE INCANDESCENT LAMP AND ITS MANUFACTURE.*

BY GILBERT S. RAM.

(Concluded from page 643.)

Relation between Light and Power.

It has already been stated that the light given out by an incandescent filament increases, after a certain temperature has been attained, at a much greater rate than the power spent in the filament. The relation of the light to the power, or to the pressure or the current, has been the subject of much study and speculation. Many and various formulæ have been given

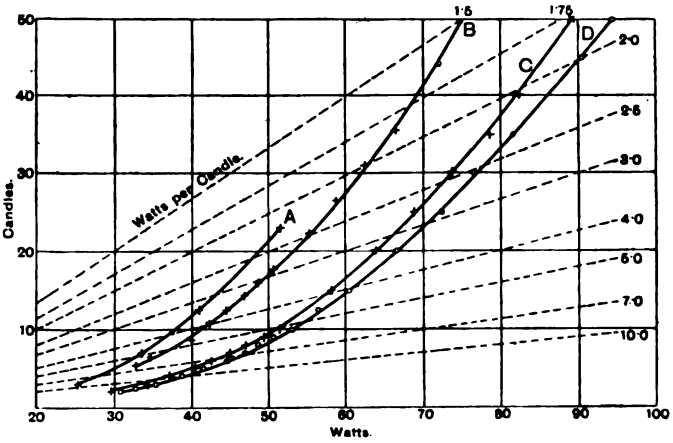

Fig. 41.

by different investigators. Some of them are nearly correct when applied to certain lamps, but are found to be quite useless when applied to others. No formula yet given appears to satisfy all cases. The reason probably lies in the imperfections of the lamps. The filaments of different lamps vary in their behaviour at different temperatures, and the vacuums also vary.

In 1882 Prof. A. Jamieson showed that the candle-power of incandescent lamps was approximately proportional to the sixth power of the pressure, and, therefore, to the sixth power of the current, since the resistance of the filament when incandescent does not alter much.

The most recently published tests have been carried out under the direction of Prof. Ayrton, at the Central Institution of the City and Guilds of London, and are published in part

* Abstract from a book to be published early next month by *The Electrician* Printing and Publishing Company (Limited). All rights of republication reserved.

Digitized by Google

in *The Electrician* of July 15, 1892. These tests are valuable, as they appear to have been carried out with great care to eliminate various errors, and the observations were made by three observers.

It is shown by these tests that there is a definite relation between the logarithms of the candle-power and of the volts, amperes, or watts respectively of each lamp.

As, however, the tests referred to are not carried above the temperature of about 4 watts per candle-power, the author introduces here some tests which he has made up to a much higher temperature.

The lamps B, C, D, are of Edison-Swan manufacture, and lamp A is an unflashed amyloid filament lamp, the test of which was, however, not carried very far.

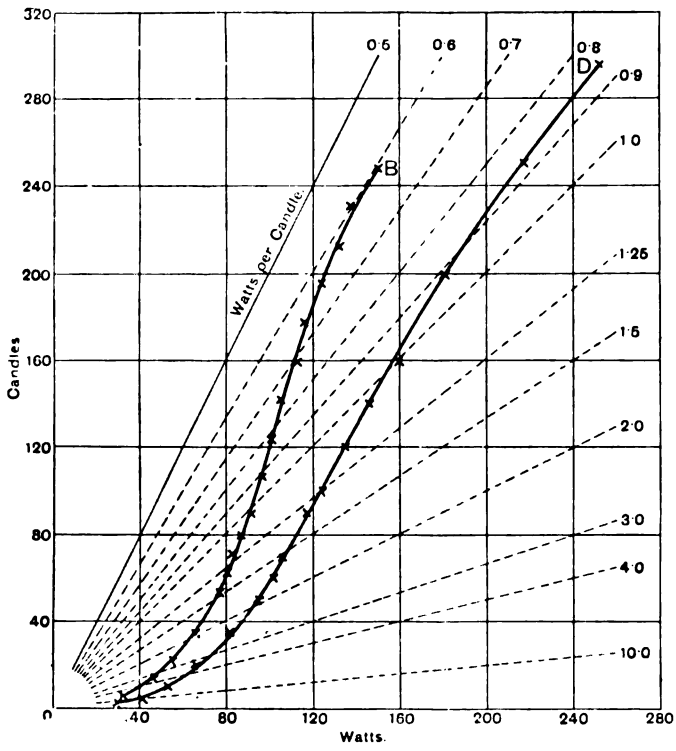

Fig. 42.

Fig. 41 shows the curves of watts and candle-power up to about 2 watts per candle-power, and Fig. 42 shows the results of lamps B and D run up to their breaking points. The dotted lines show the watts per candle-power.

It will be noticed that both the curves (Fig. 42) turn over at the higher readings. This is caused by the disintegration of the filament and its consequent change in emissivity and resistance, and by the blackening of the bulb. The direction of the curves above the point where rapid disintegration begins depends, among other things, upon the length of time during which the lamp is kept at each temperature while the observations are being made. The curve of a lamp which is kept at 1 watt per candle power for some time may, for instance, be made to bend over so much that it will never reach 0·9 watt per candle-power, as the lamp will break before arriving there. It will be noticed that lamp B attains a much higher efficiency than lamp D. The observations at the higher readings in each case were, however, made as quickly as possible.

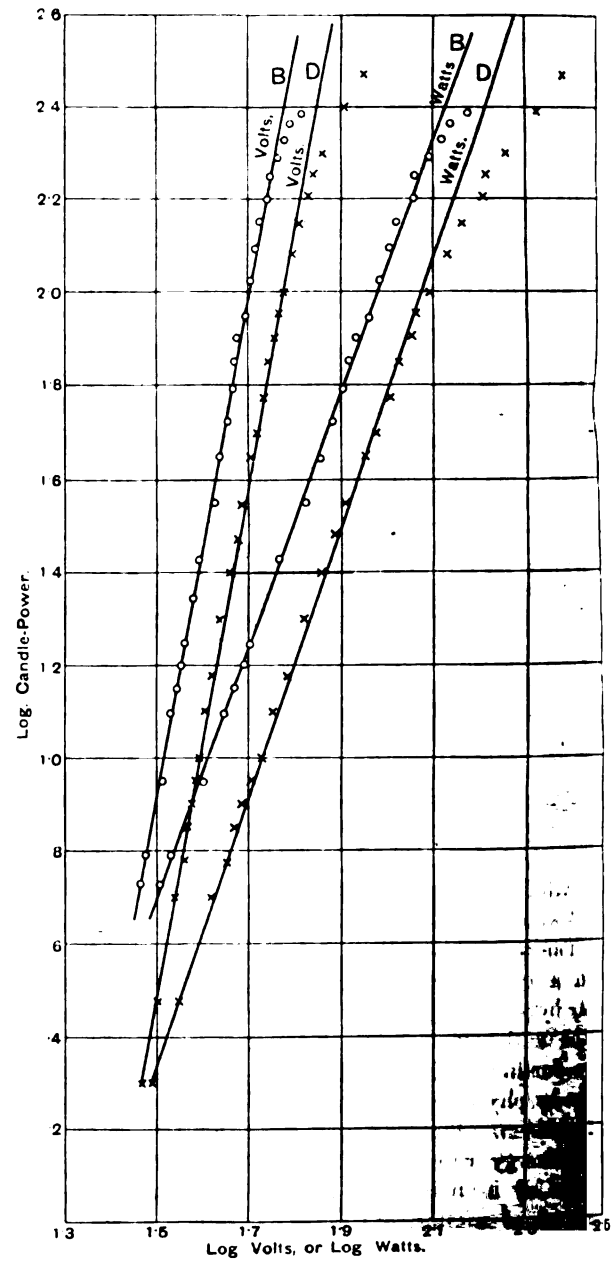

Fig. 43

Fig. 43 shows the relation between the logarithms of the candle-power and of the volts and watts respectively. Up to the point where the lamp begins to rapidly deteriorate it will be noticed that the observations in this figure lie nearly in straight lines. Sufficiently so to suggest that they ought to be exactly in straight lines. Assuming that they should do so, the expression $C.P. = a\,V^n$. Where C.P. = candle-power and V = volts, a and n, being constants, would enable us to find the candle-power at any voltage when the value of a and n is known.

Digitized by Google

In order to find the value of a and n for any lamp two observations at least must be made.

If c.p. = candle-power at the lower reading,
" v = volts " " "
" C.P. = candle-power " higher "
" V = volts " " "

then
$$n = \frac{\log \frac{\text{C.P.}}{\text{c.p.}}}{\log \frac{\text{V}}{v}},$$

and
$$a = \frac{\text{c.p.}}{v^n} = \frac{\text{C.P.}}{\text{V}^n}.$$

The observations, from which the value of a and n are obtained, must be made with the greatest care, and should

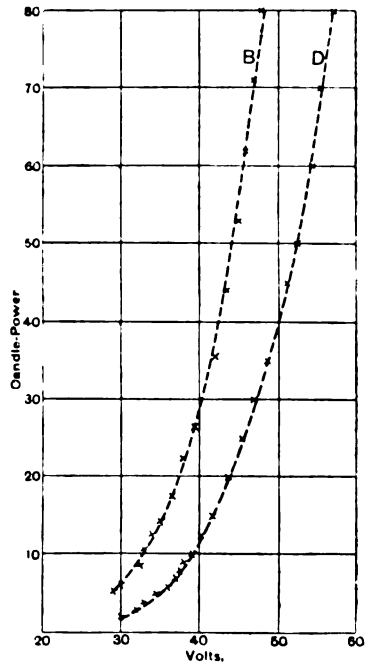

Fig. 44.

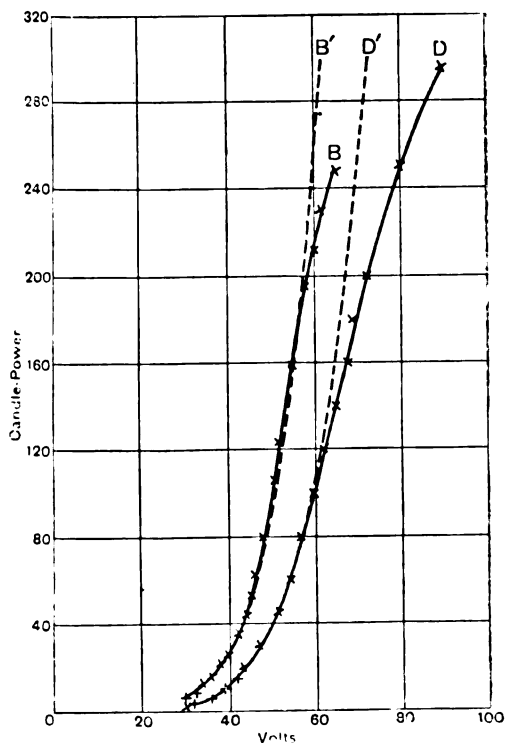

Fig. 45.

be as wide apart as possible. A very slight error in the test will give a wrong value to the exponent n, and will make the calculated results quite wrong.

In the case of lamp B, taking the readings of 30 volts 6·2 c.p., and 55 volts 158 c.p., the value of n is found to be 5·35, and $a = 7·76 \times 10^{-8}$.

In the same way for lamp D, at 39 volts 10 c.p., and 57 volts 80 c.p. $n = 5·51$ and $a = 1·695 \times 10^{-8}$.

In Figs. 44 and 45 the dotted curves show the values calculated on the above basis. The crosses mark the observed values. Over the lower portion of the curves the observed and the calculated values lie very close together. In Fig. 45 it will be seen that the curve B representing the actual observations definitely takes a different direction from B', representing the calculated values at about 180 c.p., or at an efficiency of 0·65 watt per candle. The curve D separates from D' at 100 candles, corresponding to an efficiency of 1·25 watts per candle-power only. This would seem to show that lamp D was an inferior one to lamp B.

That great care is necessary in making the tests, for a and n can be seen in the case of lamp B. If two observations only were made, and these were, say, those at 30 volts 6·2 c.p. and 35 volts 14·2 c.p., the value of n would come out at 5·38, which is very nearly right, these two observations lying almost exactly on the straight line in Fig. 43. If, however, the tests were those of 32·5 volts 8·8 c.p., and 34 volts 12·5 c.p., the one reading of candle-power being a little low and the other a little high, the value of n would be 7·9, and the calculated results would be quite wrong. These two observations lying one a little above and the other a little below the line in Fig. 66, where they are indicated by the dotted circles, while the observations from which the correct values are obtained are shown by the full circles.

It is probable that the relation of candle-power to watts is a more constant one among different lamps than that of candle-power to volts or amperes. In the latter case the degree of constancy of the resistance of the filament throughout the range of the test has an effect upon the form of the curve, whereas in the former case it has no such effect.

LAMP-HOLDERS.

(*Continued from page 639.*)

Having briefly reviewed in our last issue the four patents under which lamp-holders are now made in this country by licensed manufacturers, we proceed to describe some lamp-holders, ancient and modern, with special reference to the patents. The earliest practical lamp-holder in England was the cardboard contrivance of Swan. Many such holders are in existence to-day, as curiosities, but few lamps adapted for them remain unbroken. Fig. 1 is an illustration * of the lamp, sheath, and holder. The sheath on the stem of the lamp is made of black glazed cardboard with a wooden ring at the base. Thin brass springs are attached to this base by screws, which serve to connect the platinum wires from the lamp to these spring contact plates. The holder consists merely of a wooden ring with a pair of sheet brass guides into which the sheath slides; the springs lock themselves into these guides. The arrangement in several respects resembles Edison's holder, illustrated on page 639.

If any obstacles to the use of capped lamps are raised by the Edison-Swan United Company, it is possible that holders for loop lamps may again be in request. The holders themselves are still protected, it is true, assuming the validity of Swan 5,702, December 28, 1881; but they can be made for a few pence by licencees, and the royalty is but trifling. The spiral spring used by Swan for giving the "outward push" was inconvenient, and many different patterns have been used in later holders. It is still to be found in the price list of the Edison and Swan Company, and is shown in Fig. 2 full size. The use of crossed loops of spring wire was one of the first improvements. These are shown in Fig. 3, which represents one of the seven kinds made by the Edison and Swan Company. Fig. 4 shows a lamp-holder made by the General Electric Company of boxwood or ebony with crossed-wire loops.

* From Mr. G. S. Ram's forthcoming book on the "Incandescent Lamp and its Manufacture."

Digitized by Google

Fig. 5 is a holder made by Woodhouse and Rawson. The "outward push" springs are, perhaps, the best that have been offered; they depend for their effect upon the shape of the lamp

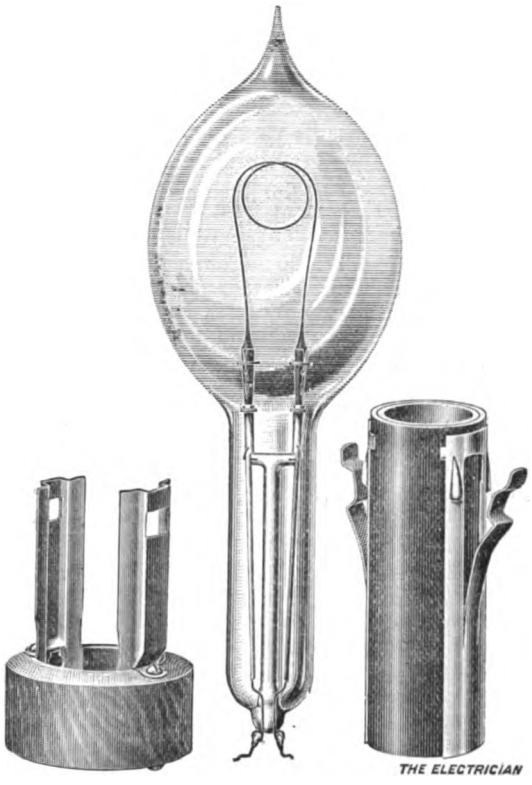

Fig. 1.—Swan's Cardboard Lamp-holder.

bulb. While there are probably thousands of users of electric light who have never seen a loop lamp, "bottom loops" are recommended for use on stiff fittings where there is much vibration. A lamp-holder has been specially designed for use in the Navy, where the firing of big guns might smash every lamp

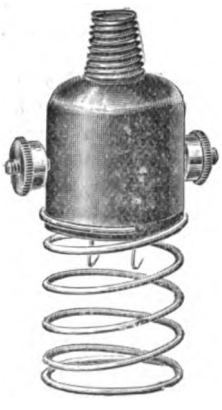

Fig. 2.—"Ediswan" Lamp-holder with Spiral.

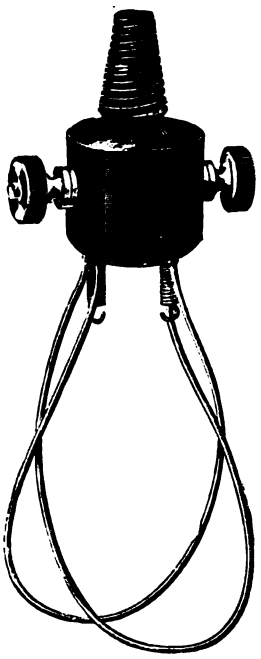

Fig. 3.—"Ediswan" Holder with Crossed Wire Loops.

in a ship if precautions were not taken. Fig. 6 shows the standard Admiralty pattern of lamp-holder. A modification of the Woodhouse and Rawson outward push springs is adopted; there are three springs instead of four, and they form part of a collar which can be set in position by set screws. Very stiff spiral springs can thus be employed. The holder consists of three parts. The one shown on the left of the figure is a shell of brass provided with a nipple screwed for $\frac{3}{8}$in. Into this shell an ebonite plug is fitted. The wires are passed through a hole in the centre, and are fastened under flat-headed screws in the front of the plug. These screws screw into brass pins, which pass through to the back of the plug, and are soldered to spiral springs, which pass through again to the front. The springs are made of No. 20 German silver wire. The ebonite plug enclosed in the brass shell fits into the slotted collar, set screws passing through the slots into the ebonite. Looped lamps have been used in many cases in order to avoid the hopeless ugliness of the ordinary socket-holder for capped lamps. Special attention has been paid to this matter by Messrs. Faraday and Sons, whose very

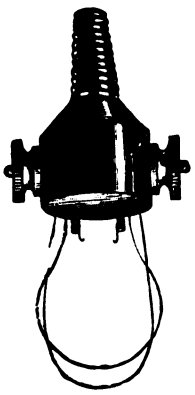

Fig. 4.—General Electric Company's Wooden Holder for Loop Lamps.

Fig. 5.—Woodhouse and Rawson Wooden Holder for Loop Lamps.

graceful fittings would be ruined by a clumsy holder, while such an appendage would hardly be noticed on a massive and gaudy polished brass "electrolier." Fig. 7 is an illustration of a holder, which was at one time made by Messrs. Faraday and Sons, but we understand that the manufacture is discontinued for the present, owing to the existence of some of the patents to which we have referred. In this holder, as in several others, the "outward push" is rigid, while firm contact is secured by spiral springs.

Holders for large lamps of 50 c.p. and upwards are made with side springs, but "lug terminals" are provided on the lamps instead of loops, and the springs exert no outward push, but on the contrary take the weight of the lamp.

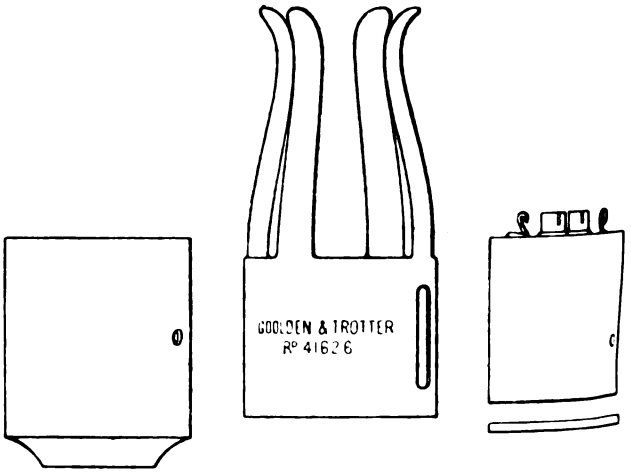

Fig. 6.—Admiralty Pattern Lamp-holder, showing separate parts.

We cannot afford space to discuss the many ingenious inventions of Mr. Alfred Swan, who has designed a large number of lamp-holders, and has constructed most of them in the peculiar form of glass which he has called vitrite. Patents No. 2,528, 1883, and 5,158, 1883, are adapted for vitrite lamp-holders for end loops or side loop lamps, but patent No. 6,319,

Digitized by Google

1884, shows a vitrite cap with contact pieces on the flat end, together with spring contacts and bayonet catch. The date of this patent is April 12th, about six weeks after Dornfeld. Many thousand lamp-holders were made in exact accordance with this patent; the weak point of them was brittleness and the difference of expansion by heat of the vitrite and of the metal. No. 9,158, 1884, of June 19th, shows several modifications, one of the most practical being the disuse of the small vitrite projections which engage with the bayonet slot in the brass tube, and the use of grooves in the vitrite material in which

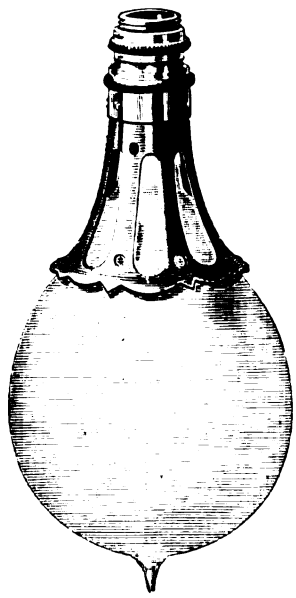

FIG. 7.—Messrs. Faraday and Sons' Holder.

depressions formed on the brass tube engaged. An elaborated form of holder is described in No. 15,025, 1884, the spring-contact pieces being made of hexagon tube with good buffer contacts. Octagon brass tube was used for the nipple which was firmly embedded in the vitrite (Figs. 8 and 9). Besides these patents, Mr. Swan had several for shade carriers and other modifications.

Before proceeding to describe the modern lamp-holders, we may refer briefly to the other patents to which allusion has been already made. The patent of J. W. and C. Swan relates to a

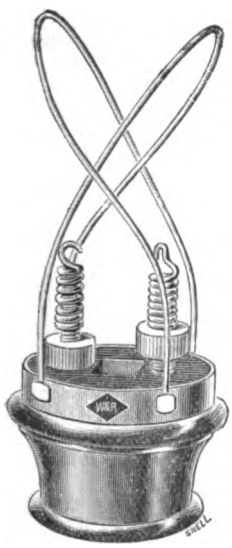

FIG. 8.—Vitrite Holder for Loop Lamps.

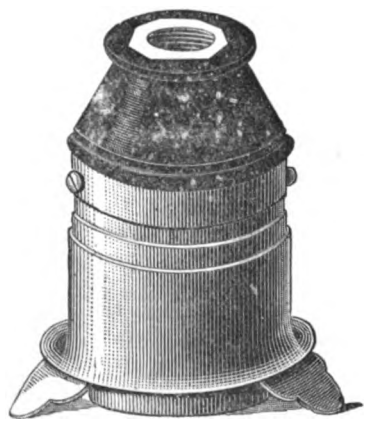

FIG. 9.—Vitrite Holder for Capped Lamps.

wooden lamp-holder with terminal loops, consisting of two or more closely-wound coils of wire ending in a hook. It was intended that the loops on the lamp should be nipped in one of the coils, which were to be formed of spring wire, with the object of making a good contact, and avoiding any spiral springs giving a longitudinal pull for the purpose of making a firmer contact. It is noteworthy that all these lamp-holders of Swan were arranged with a taper screw thread, adapted to replace an ordinary gas burner.

One other early patent remains to be mentioned, viz., that of Henri Pieper, No. 4,854, 1885. This holder consists of an open spiral of stout wire into which the Edison socket may be screwed. It is provided with a very simple switch. This lamp-holder is in common use on the Continent, but is not often seen in this country.

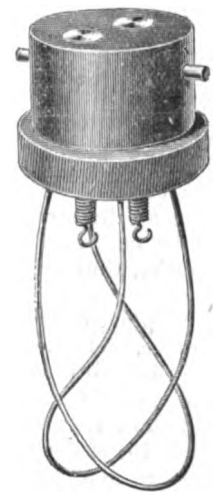

FIG. 10.—"Ediswan" Adapter for Bottom Loop Lamps and Ordinary Lamp-holder.

FIG. 11.—"Ediswan" Adapter for Bottom Loop Lamps and Edison Socket.

Having briefly reviewed the older forms of lamp-holder, we may allude to a device which was employed to bridge over the two systems of end loops and caps. When socket-holders began to come into general use, and while looped lamps were

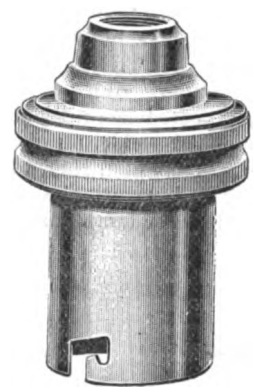

FIG. 12.—"Ediswan" No. 14 Lamp-holder.

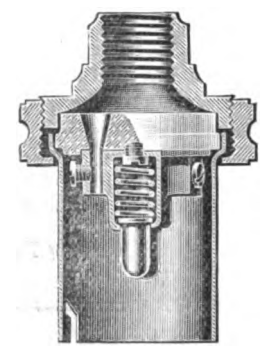

FIG. 13.—"Ediswan" No. 14 Lamp-holder (section).

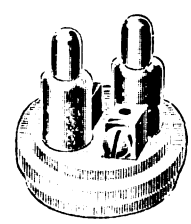

FIG. 14.—Base of "Ediswan" No. 14 Holder (front view).

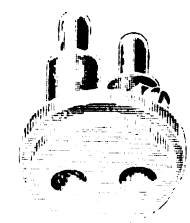

FIG. 15.—Base of "Ediswan" No. 14 Holder (back view).

still common, an adapter for fitting looped lamps to socket-holders was very convenient. Such adapters are shown in Figs. 10 and 11. Whether such adapters may be said to form part of a lamp-holder or no we cannot venture to decide, but if the Edison-Swan Company propose to keep their lamp-holder patents in force with strictness it seems possible that the device may

Digitized by Google

be, at all events for foreign manufacturers, a matter of some importance. Seeing that so many firms have taken licences for the manufacture of lamp-holders, litigation under these patents is extremely unlikely. We, therefore, have less hesitation in commenting upon the possible result upon glow lamps made by other makers, whether at home or abroad. Since the Edison patent covers all metal contacts which are attached to the base of a lamp, it is difficult to see how lamps can be provided with caps suitable for use with socket holders. If the licence to make lamp-holders includes the right to make caps and to fit them on to the lamps, there will be no difficulty, and we hope, but are not confident, that this will be the case. The Edison and Swan United Company have as yet given no indication whatever of their course of action with regard to these patents, nor is there any reason why they should do so.

We may now turn to some well-known lamp-holders at present used in this country. They may be divided into two classes, although the distinction is not always recognised, viz., for front wiring and for back wiring. Where a lamp-holder is to be screwed to a bracket, or other fitting, it is obvious that no connections can be made at the back of the base without some special arrangement for getting at the terminals. But where a pendant is used, a cap can be unscrewed from the back of the holder and pushed up the wire, thus exposing the terminals at the back.

There seems to be but little room for improvement in the standard lamp-holder of the "Ediswan" make, and known as the No. 14 holder of the Edison and Swan United Company. It is a holder of the front-wiring class, and is clearly shown in Figs. 12 to 15; the construction is so well known that description is unnecessary. The base (Figs. 14 and 15) of holders of this kind has been made by different makers in a variety of different materials. Now that the manufacture of white porcelain has been carried to such a perfection, allowing very accurately moulded pieces to be produced, this material leaves little to be desired. Steatite, slate, and even vulcanised fibre have been used. This latter material, which no doubt offers a fair insulation so long as it is kept dry by the warmth of the lamp, is now only used, so far as lamp-holders are concerned, for key sockets or switch-holders, and other more or less complicated devices. The blocks into which the conductors pass from the back through the taper holes, and to which they are secured by set screws, are made in one piece, in the "Ediswan" pattern, with the barrel of the spring plunger. With a small amount of care, as may be reasonably expected from gas-fitters and ironmongers' men, there is no danger of accidental contact between loose strands with this holder. The union ring, which holds the barrel to the back collar, and keeps the whole together, seems in this as well as in all other lamp-holders of this pattern, to be rather heavy.

(To be continued.)

PRIMARY BATTERIES IN THEORY AND PRACTICE.*

BY W. R. COOPER, M.A.

PART I.

(Continued from page 638.)

Polarisation.

Polarisation is a more serious defect than local action, as far as the utility of a cell is concerned. The latter is simply a waste of energy, but does not diminish that which is useful except as a whole; the former results in no waste, but diminishes the energy which is available at any moment.

Polarisation may occur whenever the chemical change is a reversible one, or when the action is such that the conditions are equally favourable to its reversal. Such is the case in the simple voltaic element, consisting of Zn, Cu, and dilute H_2SO_4. The Zn is dissolved and hydrogen is liberated at the copper plate, or

$$Zn + H_2SO_4 = ZnSO_4 + H_2.$$

But the reaction may also take place in the opposite direction, for the hydrogen is a free agent, and we may have the reverse change:—

$$H_2 + ZnSO_4 = H_2SO_4 + Zn,$$

the zinc sulphate being reduced, and zinc being deposited on the copper plate.

The change in the negative plate also results in a transition resistance, and the introduction of a different contact force between the plate and the electrolyte. The former is generally neglected, but the latter is of importance. If a plate that has been polarised by a film of hydrogen is removed, it is found to be electrically different to an unpolarised plate of the same kind, being positive to it. This affords a further proof of contact force. The same phenomena may be produced by gas that is not deposited electrolytically. If a plate of Pt is placed in an atmosphere of hydrogen it absorbs the gas, and is found to possess the same properties as a polarised plate. The polarisation is partially removed by washing the plate with water or KOH, and is wholly destroyed by boiling in HNO_3, or by ignition.

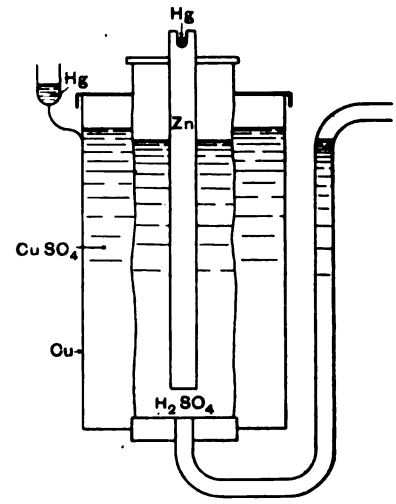

FIG. 5.—Daniell's Cell.

In 1836 Daniell gave an account of experiments that he conducted with a cell consisting of Zn, Pt, and H_2SO_4. He found that the current fell off very rapidly, but recovered at once upon boiling the platinum plate in HNO_3 or HCl. The longer the cell was in use the more readily did the polarisation occur. This is no doubt due to the increased quantity of $ZnSO_4$ present, Zn being then more readily deposited by the hydrogen. If allowed to stand the cell recovers; for the hydrogen displaces more Zn or combines with free oxygen, and the Zn deposited on the platinum plate is dissolved by local action.

Upon allowing the cell to run for 30 hours, Daniell found the current to fall off completely, and a very considerable deposit of zinc upon the platinum. To remedy this defect he conceived the idea of adding a substance which the hydrogen should precipitate in preference to the Zn, and selected $CuSO_4$ as the most suitable. This cannot be simply added to the H_2SO_4; for, although the Zn be amalgamated, sufficient local action occurs to liberate hydrogen, which would immediately act upon the $CuSO_4$ and deposit Cu on the Zn rod.

Daniell, therefore, constructed a cell consisting of a copper cylinder, within which was a membranous tube of ox gullet. The outer vessel contained the solution of $CuSO_4$; the inner one contained the Zn rod and dilute H_2SO_4. From the lower part of the inner tube there passed a glass syphon, as shown in the figure, by means of which the resulting $ZnSO_4$ might be drawn off as fresh acid was added. In this manner a very constant current could be maintained for any length of time, provided the $CuSO_4$ were maintained saturated.

The ox gullet was soon replaced by the ordinary porous pot, and it was found unnecessary to withdraw the $ZnSO_4$ that is

* Paper read at a Students' Meeting of the Institution of Electrical Engineers, May 19th.

Digitized by Google

formed. A solution of this salt is now very generally employed instead of H_2SO_4, and it is only necessary to maintain it sufficiently dilute to ensure the ready removal of the salt from the zinc rod on formation.

The very great difference between the power of a Daniell cell, and that of a cell without a depolariser, is strikingly shown by the curves of discharge as given by Prof. Carhart (*see* Fig. 6). The former, however, is not quite free from polarisation, and it is found that it depends upon the current density employed.

There are two defects in the Daniell cell. The porous pot increases the resistance, and the $CuSO_4$ in time passes by osmotic pressure to the Zn upon which the Cu is deposited. On this account it is inefficient and unsuitable for prolonged action.

Any substance, liquid or solid, which is capable of combining with hydrogen may be used as a depolariser. Thus, any substance containing an oxidising agent such as peroxides, the halogens, HNO_3, chromic acid, bichromates, sulphur, &c., are suitable for the purpose. For example, the Grove contains HNO_3; the Leclanché, MnO_2; the Edison-Lalande, CuO; and so forth. The great advantage of a solid depolariser is that the porous pot may generally be dispensed with.

These theories of polarisation are at the best unsatisfactory. The resistance introduced along with polarisation appears to have been neglected, and it is not easy to distinguish between

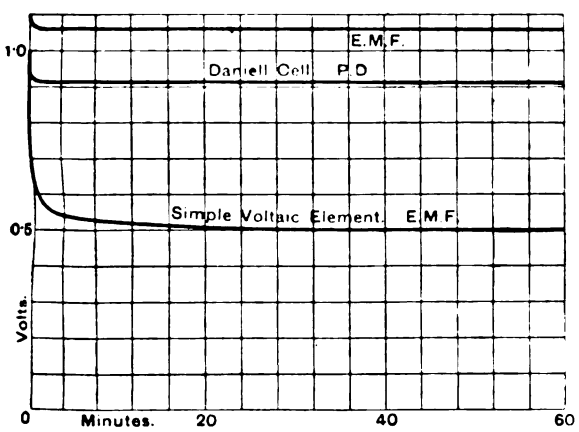

FIG. 6.—Polarisation Curves.

the two. There is no reason why polarisation should not be due simply to back action, if we consider the actions occurring in a chain (rigid, as it were), so that corresponding actions occur simultaneously at either end. Upon the formation of a molecule of $ZnSO_4$, the hydrogen at the other plate may be regarded as simultaneously reacting upon it, being unaffected by the intervening molecules.

Hydrogen is not the only polariser. In the Daniell cell, employing $ZnSO_4$, zinc is the polariser. In the cell already referred to (*see* Fig. 1), consisting of copper, NaCl, and $CuCl_2$, only the copper and the NaCl are the essential elements. Sodium is the polariser, and the $CuCl_2$ is simply the depolariser.

Thermo-Chemical Relations.

A clearer idea of what takes place in a cell is obtained by considering the thermal changes in the way indicated by Lord Kelvin in 1851, when he brought forward his dynamical theory of electrolysis. Let e be the electro-chemical equivalent of one of the ions of the electrolyte supplying energy to the circuit, and θ the heat produced by the combination of unit weight of this ion with the second of which the electrolyte is composed; then, if J is Joule's equivalent, the total quantity of work per second performed by the chemical change is $J\theta e . Q$, Q being the quantity of electricity passing. But the work is also equal to E Q where E is the E.M.F. of the cell. Hence:

$$E Q = J \theta e Q;$$

or, $$E = J \theta e \quad \text{in C.G.S. units,}$$

showing that the E.M.F. can be determined from a knowledge of the chemical changes involved, and that it is directly proportional to the heat of combination of the electro-chemical equivalent of the ion, or of that quantity of the ion which is deposited in unit time by unit current.

This formula may be put in a somewhat more convenient form. Since Joule's equivalent is 41·6 millions, we may write

$$E = 4{\cdot}16\, \theta e \text{ volts,}$$

the ampere now being the unit of current. Also the electro-chemical equivalents and the chemical equivalents are proportional. Hence, if the electro-chemical equivalent of hydrogen is known, that of any other element is obtained by multiplying this by its chemical equivalent. The electro-chemical equivalent of hydrogen is 0·00001036. Hence

$$\theta e = 4{\cdot}16 \times 0{\cdot}00001036\, \theta' = 0{\cdot}000043\, \theta'$$

where θ' = heat of combination of one chemical equivalent of the ion. If E = 1, we see that 23,200 heat units correspond to one volt, or 46,400, if the atomic weights of bivalent elements are the chemical equivalents employed, or double the atomic weights of the univalent elements.

A large number of determinations of the heats of combination have been made by Thomsen; and, since the electro-chemical equivalents of the ions are well known, it is not difficult to calculate the E.M.F. of any particular cell. For example, if we deal with gramme molecular weights, the heat of formation of $ZnSO_4$ from Zn and dilute H_2SO_4 amounts to 37,730 gramme centigrade heat units; or, in other words, this amount of heat is evolved by the combination of 65 grammes of Zn with 98 grammes of H_2SO_4 to form $ZnSO_4$. Now the equivalent of one volt is 46,400 heat units. Hence the calculated E.M.F. of the simple Zn – Cu couple in dilute H_2SO_4 amounts to

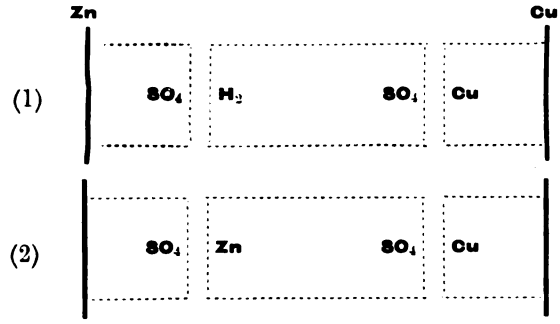
$$\frac{37{,}730}{46{,}400} = 0{\cdot}8 \text{ volt.}$$

If a depolariser is employed, as in the Daniell cell, energy is thereby added to the circuit, for there are now two chemical changes involved instead of one. $ZnSO_4$ is still formed; but the liberated hydrogen breaks up the $CuSO_4$, and thus there is a further evolution of heat, amounting to 12,400 units. The total evolution of heat is therefore 37,730 + 12,400 = 50,130, giving an E.M.F. of

$$\frac{50{,}130}{46{,}400} = 1{\cdot}08 \text{ volts,}$$

which is in agreement with experiment.

The result is the same if the sulphuric acid is replaced by a solution of $ZnSO_4$. In the one case H_2SO_4 is broken up, and is reformed, and in the second case $ZnSO_4$ undergoes the same change:—



In both cases these changes neutralise each other, and the energy of the system is unaffected. This, coupled with the fact that the energy is transferred, enables such an electrolyte to be used.

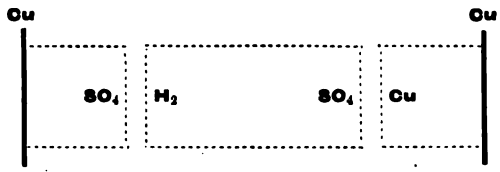
There is, however, one point of which no account is taken in this investigation. It is tacitly assumed that amalgamated zinc is in every way equivalent to zinc in the ordinary condition, but there appears to be very little evidence strictly in favour of this assumption. If the total energy is unaffected, it is reasonable to suppose that the zinc forms a distinct substance with the mercury, and that the heat evolved as the inner particles come into amalgamation is abstracted from the system as the atoms pass from the amalgam to form $ZnSO_4$.

It is often found that the calculated E.M.F. is at variance with that which is observed. For example, the calculated

Digitized by Google

E.M.F. of the De la Rue cell is 1·18 volts, whereas the observed value is 1·05 volts; in the case of the Grove the calculated value is 2·08 volts, whereas observation gives 1·95 volts. The discrepancy may be assigned to two or three causes. It is improbable that the theory is false; it is obtained by equating the same quantity of energy in two different forms, and there can be no error in so doing. If the thermo-chemical data are correct we can only conclude that we are dealing with a different quantity of energy to that which we had supposed. In other words, chemical changes in the cell have been omitted or misunderstood, and when we come to a point like that it is hard to say what we do understand. For example, we may be dealing with an hydrated salt or acid instead of the substance that we suppose. In the case of the Grove, the acid may be of a different strength to that with which the heat of combination was determined, or we may be dealing unconsciously with bodies which are present and entirely disregarded.

Examples of such cases are easily found. If a strip of copper is placed in a test tube containing dilute H_2SO_4 in the lower part and $CuSO_4$ in the upper, electrolytic action sets in: copper is dissolved by the H_2SO_4 and deposited by the $CuSO_4$. We have apparently the change which is expressed below :—

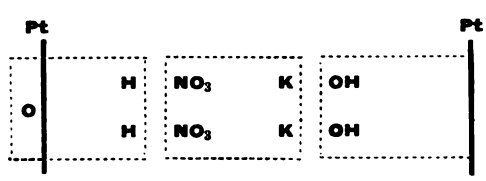


Now $CuSO_4$ has a negative heat of combination of about 12,000: *i.e.*, copper will not dissolve in H_2SO_4 without the aid of heat. And even supposing it had a positive heat of combination, we are here concerned with two electromotive forces in the same circuit which are equal and opposite; viz., that due to the formation of $CuSO_4$, and that due to its decomposition. The cell then cannot work under the assumed conditions. But if we suppose oxygen to be present in the H_2SO_4, as it certainly is, then we are dealing with different conditions, and it is possible for the cell to work.

As another example we may take Becquerel's cell, already alluded to (*see* Fig. 2), which consists of a porous pot containing HNO_3 standing in an outer vessel filled with KOH solution. Two platinum plates are employed, and it is supposed that the current is generated by the interaction of the two electrolytes. But it is impossible to obtain a current by the neutralisation of an acid with an alkali. We have, of course,

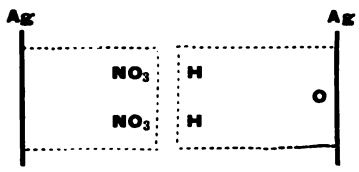
$$KOH + HNO_3 = KNO_3 + H_2O,$$

but nothing is liberated, whereas the liberation of an ion is essential to the working of a cell. It is, as it were, a closed circuit, and there is no transfer of energy. Yet the cell gives a current. This is probably due to the presence of atmospheric oxygen and upon this supposition the change may be represented thus :—



The hydrogen of the nitric acid would then combine with the oxygen in solution at the Pt plate to form water; KNO_3 would result, and hydroxyl would break up at the other Pt plate into water and oxygen. Faraday observed in his "Experimental Researches" that such a cell could not work unless one of the plates were replaced by zinc; but such a change reduces it to one of the ordinary form, either the HNO_3 or the KOH being then superfluous.

Reference has already been made to the solution of metals by electrolytic action and the double action of solvents. A good example of the latter is afforded by the solution of silver in HNO_3. It is well known that this metal will not dissolve simply in HNO_3; but it does so if a little nitrous acid is present, which apparently supplies the necessary depolariser. Assuming this to be the case, the reaction may be represented as follows :—



the oxygen being probably derived from a nitrous compound, the remaining part of which is not indicated.

Similarly, amalgamated zinc dissolves in dilute H_2SO_4 upon the addition of HNO_3. A voltaic cell is formed. Part of the zinc is acted upon by the H_2SO_4; another part forms, as it were, the external circuit and the other metallic element with the depolariser which is HNO_3.

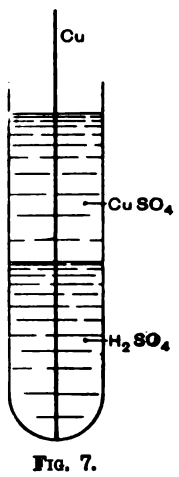


FIG. 7.

It will be noticed that Kelvin's "Dynamical Theory" takes no account of the negative plate, for no chemical action occurs there. It therefore follows that no variation in the E.M.F. should be caused by changing the negative element. For example, the E.M.F. of the Grove should be the same as that of the Bunsen, but it is generally found to be somewhat greater. The carbon of the Bunsen may possibly have some effect on the acid, and it is probable that they would give the same result if compared under truly comparable conditions.

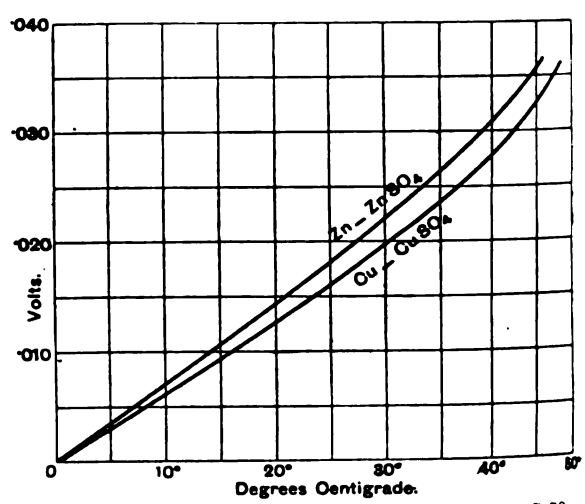

FIG. 8.—Thermo-Electric Power of $Zn - ZnSO_4$ and $Cu - CuSO_4$.

From these considerations it also follows, if the contact theory be true, that the differences caused in the contact forces with the electrolyte and the positive element, by the introduction of a different negative plate, should balance, so that the sum of the forces of contact throughout the cell should remain unchanged. This seems somewhat improbable.

Temperature Coefficients.

Since the heat of combination of a compound varies with the temperature at which it is determined, it is theoretically

Digitized by Google

possible to determine by this means the temperature coefficient of any given cell. Unfortunately thermo-chemical data have not been studied as yet with sufficient care to enable this to be done. But from what we do know, it appears that the coefficient may be positive or negative.

There is another way of looking at temperature coefficients which is of interest. We may suppose that the variation in

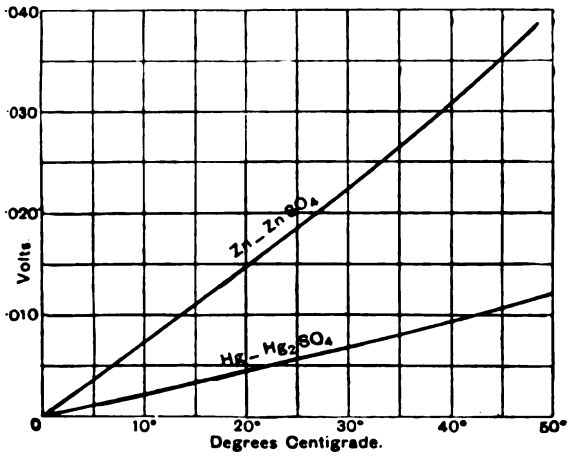

Fig. 9.—Thermo-Electric Power of $Zn - ZnSO_4$ and $Hg - Hg_2SO_4$.

E.M.F. *is due* to thermo-electric couples. There may be a certain E.M.F. set up between one of the plates and the electrolyte, and a similar one at the other plate, if the temperature at that part is also varied. This theory is taken up by Prof. Carhart ("Primary Batteries," by Prof. H. S. Carhart), who, however, neglects the possible E.M.F. caused by the junction of the electrolytes, which, by experiment, appears to be extremely small.

The thermo-electric power, or the potential difference per degree rise of temperature, was determined for both $Zn - ZnSO_4$ and $Cu - CuSO_4$, as shown by the curves that are reproduced (*see* Fig. 8). It is seen that the thermo-electric power of $Zn - ZnSO_4$ is slightly greater than that of $Cu - CuSO_4$. Since these couples oppose each other, it follows that the resulting change in E.M.F. should be very small: the calculated value is only 0·00006 volt per degree, the E.M.F. falling by this amount for rise of temperature. The actual temperature coefficient Prof. Carhart found to be 0·000067, which agrees very fairly with the above.

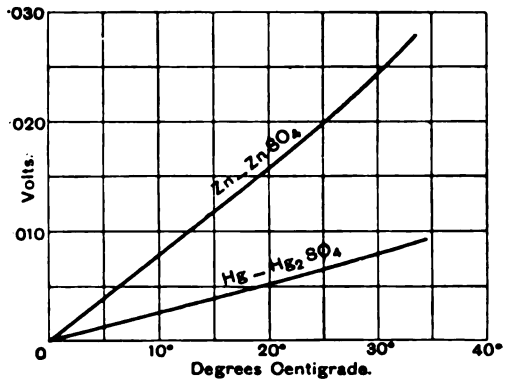

Fig. 10.—Thermo-Electric Power from Clark Cell.

The temperature coefficient of the Clark cell, calculated in the same manner, amounts to 0·000381, which is very much lower than the generally accepted value, but agrees very closely with the value 0·000386, which Prof. Carhart found for the cells in his possession. The curves which are reproduced show the results obtained. One of them (Fig. 9) simply gives the thermo-electric powers observed. The other (Fig. 10) gives the differences of E.M.F. observed by separately heating the junctions in an experimental Clark cell.

(To be continued.)

COMPENSATING GENERATORS AT DERBY.

The theory of the special form of armature winding, and of field-magnet design, by which Mr. W. B. Sayers arrives at his self-exciting dynamo, has been fully discussed in recent numbers of *The Electrician*. On pages 60 and 66 of the issue of May 19, 1893, we gave an account of Mr. Sayers' Paper before the Institution of Electrical Engineers. On September 22nd and 29th we referred to his British Association Paper, and to the actual dynamos which are now running at the Derby railway station electric light works. We are now able to give a set of scale drawings (Fig. 1), showing the elevation, transverse section and plan of one of these machines, which, as it will be remembered, are the joint invention of Messrs. W. B. and J. Sayers.

Two of these machines, which have been manufactured by Messrs. Mavor and Coulson, of Glasgow, are now employed as compensating machines on the three-wire lighting circuit of the Midland Railway Station at Derby, and similar machines are in use in other places for the same purpose. In his British Association Paper, Mr. W. B. Sayers explains the mode of action of these compensators, in balancing the disturbance of

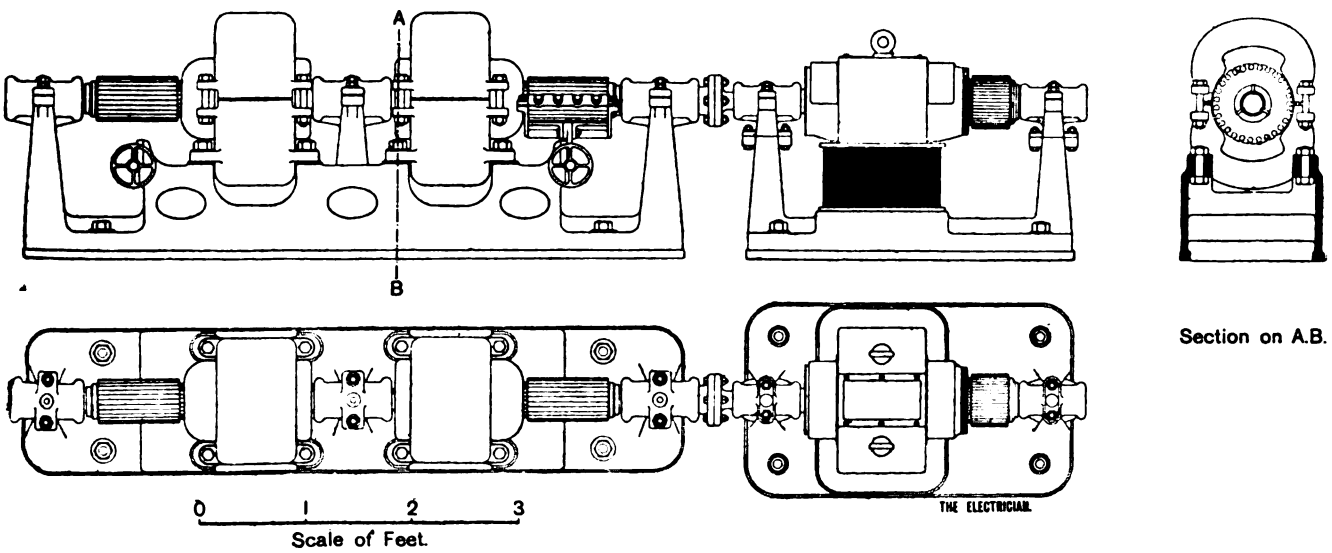

Fig. 1.—Elevation, transverse section, and plan of Sayers' Three-Wire Compensator.

Digitized by Google

pressure-equilibrium at the feeding points, which is caused by upsetting the equilibrium of the loads on the two sections of the three-wire system.

Mr. Sayers arranged a diagram (Fig. 2) which illustrates the nature of the disturbance. In order to make it clearer he has taken an extreme case, and supposed there to be double as much current flowing on one side as on the other, so that half the total current (200 amperes) is returning by the balancing wire, which is supposed to have a cross-section equal to one-half that of either of the outer feeders. Under these conditions, if the feeders have the resistances indicated in the

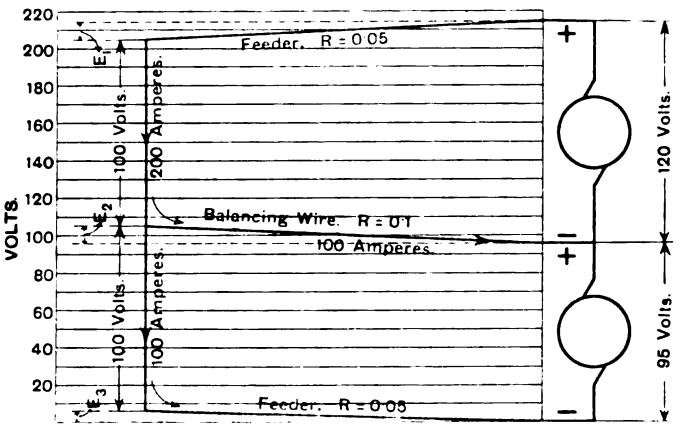

FIG. 2.

E_1 = Fall of Pressure in Positive Feeder = 200 × 0·05 = 10 volts.
E_2 = do. Balancing do. = 100 × 0·1 = 10 volts.
E_3 = do. Negative do. = 100 × 0·05 = 5 volts.

diagram there will be a fall of 10 volts both in the feeder and also in the balance wire as regards the overloaded side; but the fall of 10 volts in the balance wire counts as a rise of 10 volts as regards the underloaded side; and as the fall in the feeder on the underloaded side is only 5 volts it is clear that the generator on the underloaded side must only give 95 volts, in order that the pressure at the distant end shall be 100 volts, whereas the generator on the overloaded side must give 120 volts to secure the normal of 100 volts at distant end. On referring again to Fig. 2 it will be seen that the compensator through which the current to the feeder on the overloaded

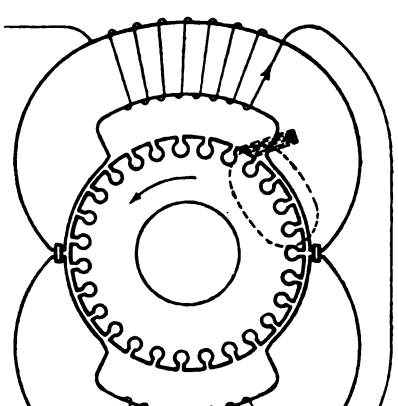

FIG. 3.

side passes must raise the pressure 20 volts, while the compensator through which the current to the underloaded feeder passes must *lower* the pressure 5 volts, the main dynamos being kept at constant pressure of 100 volts. It therefore follows that the compensator must be capable of running sparklessly, not only when the magnetic induction through the armature and keepers is proportional to the current flowing, *i.e.*, the ordinary conditions of a series machine, but also when there is a current through the armature, but no *effective* magnetic field or even a magnetic field in the opposite direction to what may be called the normal, so as to reduce the pressure. It so happens that these machines fulfil these conditions to an almost perfect degree. Fig. 3 represents a section through armature and keepers of one of the machines constructed. Suppose a current flowing through the winding around the keepers sufficient to neutralise or overbalance the effect of the current through the armature winding so far as the generation of E.M.F. is concerned, there will still be a considerable reversing field in the right direction due to the effect of the armature coils which are under the pole-pieces; or what is known as the cross-induction. This is indicated in one of the pole-pieces by the dotted line; the position of the brush is also indicated. The current in the balancing wire is made to assist this cross-induction in the machine which requires its E.M.F. to be raised, and to oppose it in the other machine, in which the voltage is to be lowered.

THE DEVELOPMENT OF ELECTRIC MACHINE TOOLS.*

BY S. S. WHEELER.

There can be no question that some mechanical engineers and electricians are far from convinced that it is desirable to modify the form of the tool so as to admit of a blending of the two elements in one. Many able engineers think it is well enough to bring the power cheaply and conveniently to the tool, but they then prefer to keep separate the motor and the driven mechanism. In traction there are some authorities who are wedded to the old practice of having the motive power in a freely detachable engine, while, as a matter of fact, a marked tendency in all the successful traction work by electricity has been toward having the motive mechanism in each car, and I do not overstate the case when I say that almost all distribution of power in the future promises to be done on the same principle. Be this as it may, it has seemed to my associates and myself that we realised the highest efficiency, economy, and flexibility in embodying our power within the tool, so that each tool might itself be fairly called an electric motor. It will, perhaps, be remembered that early this year our motor shops were transferred to Ampère (N.J.), and it is there that the tools now under consideration have been installed. If we were not satisfied with them we knew that nobody else would be, and we were perfectly satisfied to find out the difficulties ourselves, and solve the new problems that inevitably spring up rather than leave our customers to doubt our judgment because we had been led by enthusiasm to put some imperfect novelty on the market. Unfortunately, that happens too often in electrical development. Before proceeding to the descriptions, I pause simply to note the readiness with which these ideas have been applied. For example, as one result of the accident to the propeller shaft of the "Umbria," it has been influentially urged that as every steamer has an electrical plant it ought to carry electrical machine tools ready at a moment's notice, and able to go into a very small space. It is said that, with a portable electric drill for instance, the holes in the "Umbria's" shaft could have been bored in one-fifth the time that was actually consumed, and with infinitely less trouble. Anyhow, it is obvious that a self-contained electrical machine tool is much handier than would be two sets of mechanism to do the same work under the same circumstances.

I have already said that these tools were all built for the new works of the Crocker-Wheeler Electric Company, where the electrical method of distribution and driving has been broadly introduced. As the main line shafting, about 1,000ft. in all, previously in use in these works was removed as a preliminary to their occupancy of the property, it became necessary when moving there to make provision for the electric driving of the ordinary belt-driven tools from the old shop, or at least of such of them as could be equipped with advantage. A few, chiefly lathes, were belted in groups of five to single lengths of shafting, driven by motors bracketed to the columns of the building. In these cases the shafts were placed end to end in line, so that they could be coupled in pairs, threes, &c., in case it was found that larger divisions were more economical in driving. So far this has not been found desirable, on account of the greater flexibility of the present arrangement. The greatest difficulty in the introduction of motors on tools is due to the wide range of speeds met with in different tools, which is made still worse by the fact that almost without exception all industrial devices have been designed, improved, &c., solely with reference to belting, its conditions and limitations. The writer is strongly impressed with this, from experience so far had, in specially designing a few electric tools. But this is entirely

* Abstract from the *Electrical Engineer* of New York.

Digitized by Google

overcome, and in each case several important advantages are secured, by starting at the bottom in design, and making a machine with reference to the high, quiet speed of the motor spindle. That is to say, in most cases more difficulties have been met and provided for, in designing and developing a given belted machine, say a profiler, in making a frame and bearings to stand the strain of the belt, in carrying the belt to the *travelling* tool, and in gearing up for sufficient tool speed, than would be the case in building one for a motor where the cutter holder can carry the motor and there are no strains or jerks. The speed-increasing gearing would simply have to be reversed, permitting the motor to run faster than the tool, instead of slower as in the case of the belt. And yet if we are compelled to start with a profiler already built, it is not easy to get the full advantages of simplicity in driving by motor to which we are entitled, just because the speed ratios of the gearing are opposite to what is now required, and everything is arranged for belts. In the case of other tools other features of a similar nature require changing.

A surface grinding machine, used in sharpening armature and other dies, was operated by two independent belts from an overhead countershaft; but when, by the removal, electric power became available in all parts of the shop, the countershaft was done away with, and a ¼ H.P. constant speed motor was mounted directly on the sliding carriage which supported the grinding wheel, and whose cross-wise sliding motion carries the wheel to all parts of the surface to be ground. A light belt was run from the grinding wheel under two idlers to the motor pulley, and as the motor was light enough to move with the carriage, it became possible to avoid the use of a pulley with long face equal to the total motion of carriage, across which the belt travelled when the carriage moved, which was formerly required on the countershaft. The motor is supported by four bolts with check nuts, by means of which it can be raised or lowered about half-an-inch, to keep the belt at proper tension. The power required by this tool on the 110-volt circuit never exceeds two amperes, and is supplied to it by a twin conductor. Four gang drill presses were formerly driven by belts from overhead countershafts, the belts coming directly down, then turning in a horizontal direction by the means of two idle pulleys attached to the top of the press, and thence passing around a driving pulley on a vertical shaft at the back of the press, which shaft carries four smaller pulleys operating the spindles by means of four short belts, in the usual way. The driving pulley on the upper end of this vertical shaft was removed, and a motor armature slipped on in its place. The field-magnets and regulator for the motor were then fastened to the drill-press frame, completing the machine. By this means the driving power was applied directly to the back spindle of each drill-press, saving at least one-half of the power formerly required. In these machines the necessary changes of speed are effected by a switch, which throws the armature either on to the 110 or 220-volt circuit accordingly as a slow or fast speed is required, the fields remaining on the 110-volt circuit until the switch is turned entirely off, when the fields are disconnected. By this arrangement the simplest windings of motor without divisions of the field coils or series multiple switches, are made to give the required changes of speed running in either case with perfect efficiency. A common planer, built to be driven by one straight and one cross belt from a countershaft, is now operated by two short belts, neither of them crossed, from two motors placed on a shelf bolted to the top of the tool frame of the planer. This arrangement gives several new possibilities in the operation of a planer. The relative speeds of the forward and back motion of the platen can be regulated by simply turning the hand regulators of the respective motors, and the platen can be sent the whole length of the bed in either direction without being returned, by starting one motor without the other. The construction, however, was simply a make-shift to get the planer into operation quickly by the use of standard motors, and will probably be changed at convenience by the substitution of a single motor with a long shaft and two pulleys for the two belts. Since the momentum of the platen requires either a heavy armature or a fly-wheel to stop and reverse it, the effect at present is to slow the motors up momentarily and produce sparking. The drills were all formerly operated by belts from the ceiling to the countershafts attached to the base plates of the presses, from which the power was transmitted by short belts to other shafts at the top of the presses, and then by bevel gears to the drill spindles. The motors now used are supported on heavy yellow pine brackets clamped to the pillars of the presses about half way up, and the power is carried to the countershafts by short belts. On the side of each alternate truss are the three wires to which they connect and which are the main branches from the round copper rods running the length of the shop. The connections from the main bars to the branch cut-outs are made by flexible cables attached to brass clamps, similar to a lathe dog cut open on one side. The tails of these clamps drop the cables down about 3in. below the main bars, giving a clear space for crossing the other bars. At the same time the clamps furnish a ready means of making firm connection to the bars after the latter are in position. These main shafts are half-inch round copper rods in straight 20-foot lengths, joined with cylindrical or sleeve couplings soldered, the rods being attached to the under side of a line of wide planking by the largest size of porcelain hook insulators. The three rods on the right hand in the view, serve to supply either 110 or 220 volts, at all points in the shop, thus furnishing a means of running at a fast or slow speed without regulator boxes, except for small intermediate gradations. The two lines on the left are heavy insulated wires for lighting. In addition to this set of circuits, which extends throughout all parts of the main and subsidiary buildings, another set of about as many conductors runs from the engine-room to the testing room. These test bars are branched off in four directions and brought down the four sides of the room, and are again branched and carried lengthwise under every bench, so that all the different voltages and special variable circuits are available at all points in this room. The conductors at all points of branching are carried in the same relative positions and the cross-overs are made at different levels about 6in. apart, each rod being carried to a point directly under the one to which it is to be connected, and soldered into the lower end of a rectangular brass piece, the upper end of which surrounds the corresponding rod. A large drill, built especially to be operated by a motor, has the motor mounted on a cast-iron bracket, forming the cap of the drill column, thus taking the driving power out of the way of the swing of the drill arm, the countershaft having formerly been located on one side at the base of the column. The fact that by this construction it is possible to swing the drill and arm around the entire circle was taken advantage of, to make the bed-plate of the drill-press circular, so that work could be set up on all sides. After a single reduction by gearing, the motion of the horizontal shaft of the motor was communicated to either of two vertical shafts by means of a pair of bevel gears. One of these shafts carries a gear which slides the length of the shaft, following the motion of the swinging arm when raised and lowered, and which gear drives a shaft extending out the length of the arm, upon which shaft another bevel gear slides and gears with the vertical spindle carrying the drill. Another gear near the drill connects with the horizontal shaft on the arm to drive the feed mechanism. The second vertical shaft is used to raise and lower the entire swinging arm with the drill and feed mechanism, a matter requiring considerable power. When this arm is to be raised or lowered, the motor is thrown into gear with this shaft by swinging the intermediate gear away from the other shaft and into gear with it, in the same manner as the lever and back gears on a lathe are operated. If the arm is to be lowered, the direction of rotation of the motor is reversed by the reversing regulator. In the final tests of this tool at the shop a man sat on the end of the swinging arm and rode up and down with the drill. The motor used is a 1 H.P. Crocker-Wheeler standard machine.

These examples of some of our latest work will enable the reader to form a conception of the lines upon which we are working and which we believe to be fundamentally sound. The argument is that it is better to take the tool to the work than bring the work to the tool; that it is better to have the tool self-contained so that by attaching to the copper mains it is at once ready to run at maximum efficiency. In our own shops this has certainly proved true in the manufacture of machinery that does not run into excessive sizes; but it must be even more true when we consider how bulky and heavy much of the modern machine work is. Units that we all thought gigantic have come to be small, no matter what the industry is; and in order to get the various parts treated, shifted to and fro, and assembled, shops have spread out acres wide and miles long, whereas the greater availability of these electrical machine tools makes for the highest concentration of effort and the smallest area of valuable real estate, combined with the utmost utilisation of every watt that the central power plant sends out.

QUEENSLAND AND THE NEW CALEDONIA CABLE.

The following extracts on the above subject are from *The Times*:—

The Société Française des Télégraphes Sousmarins, under contract with the Governments of France, Queensland, and New South Wales, which have guaranteed a subsidy of £12,000 a year, has just completed the laying of a submarine cable between New Caledonia and Queensland.

Sir George Dibbs (the Premier of New South Wales), in the course of an interview, defended the construction of the Queensland and New Caledonia cable, declaring that it would be useful in many ways, and especially in the event of war in the South Seas. He agreed that it was necessary that the Pacific cable of the future should be under British control, but insisted that New South Wales was still at liberty to co-operate in any such undertaking. He considered that the construction of the cable to New Caledonia should show the British Government the necessity of laying a cable across the Pacific *vid* New Zealand, Fiji, Samoa, and Honolulu.

Digitized by Google

The Marquis of Ripon, in reply to the letter addressed to him on the subject by the Hon. J. B. Patterson, Premier of Victoria, expresses his regret at the action of Queensland and New South Wales in committing themselves to the laying of a cable to New Caledonia to serve as the first section of the proposed British cable across the Pacific to North America. The Secretary of State points out that this action is at variance with the views expressed by the Colonial Conference held in 1887, and lessens the chances of those Colonies which are assisting in the scheme of laying an entirely British Pacific cable. He concludes by stating that he shares the opinion of the Victorian Government that a French section in the Pacific cable might become a source of danger to Imperial and Colonial interests in time of war.

The laying of the first section of the Pacific cable, which was begun at Gomen, in New Caledonia, on August 30th, has now been completed to Bundaberg, one of the most flourishing centres of the sugar industry in Queensland, and French and English territory in the Southern seas are in telegraphic communication with each other. The cable has been laid on an entirely new line of soundings, and is reported to have found excellent resting and good bottom throughout the whole length of its course. Even the unexpected obstacle of a submarine mountain some 7,200ft. in height, which was discovered to exist upon the course originally selected, appears to have caused no serious difficulty or delay, and M. Rouilliard, the engineer-in-chief of the French Company, has received warm congratulations upon the manner in which the work of the expedition has been carried out.

It is hoped and believed by the Colonial supporters of the new line that it is a *bonâ fide* beginning of a Pacific cable which is to connect Canada and Australia, and complete the telegraphic circle of the world.

Queensland, which has always refused to subsidise the Eastern Extension Company's cable, on the ground, as has been generally supposed, of an old grudge hardly worthy of such long remembrance, has urged, in justification of her policy, that she desired to hold her subsidy in reserve for the encouragement of an alternative line, and New South Wales has now joined her in undertaking with the Government of France to guarantee the working expenses of the portion of the line which has been made. The course which the further construction of the cable is intended to take is—first, from New Caledonia to Fiji, then from Fiji to Samoa, from Samoa to Honolulu, from Honolulu to the Fanning Islands, thence boldly to Vancouver. The native rulers of the islands which are to be touched have promised substantial subsidies. The assistance of the Canadian Government is confidently counted on if the construction of the section from Honolulu to Vancouver should be brought within any measurable distance of fulfilment, and the advocates of the scheme do not despair of inducing the Governments of the other Australian Colonies which have hitherto resolutely opposed it to contribute to the guarantee. There can be little doubt that the existence of a Pacific cable connecting the eastern and western limits of the Empire with each other would be an advantage from every Imperial and Colonial point of view. There are, nevertheless, good reasons for the coldness with which the present scheme has been received by Victoria and the other Australasian Colonies which have refused with her to contribute to the guarantee. The Société Française des Télégraphes Sousmarins is a foreign company subsidised by a foreign Government. The proposed route of the cable lies in part through foreign territory. The principal value of a cable from the Imperial point of view is for political purposes, and it is evident that a line which passes at any portion of its course entirely into the hands of a foreign Power might become perfectly useless in the event of complications arising with that Power. It is not probable that any English Government would be disposed to contribute to the guarantee of a French cable, and in the absence of an Imperial guarantee it is not easy to foresee how the financial difficulties attendant upon the construction of the immense stretch of line from Honolulu to Vancouver are to be surmounted. The business to be transacted between the four and a-half millions of Australia and the communities with which the proposed cable would bring them into connection does not seem likely for many years to justify the construction of the line as a purely commercial undertaking. There can be little doubt, however, that the development of communications does stimulate as well as follow trade. The establishment of new lines of steamers has always been the forerunner of the construction of submarine cables, and if the new cable should, notwithstanding anticipations to the contrary, succeed in establishing itself upon a commercial basis, the result would be wholly a matter for congratulation to every one concerned.

TO THE EDITOR OF "THE TIMES."

SIR: It is a striking illustration of the indifference of the so-called Imperial Parliament to Imperial interests that such an obvious, urgent, and necessary Imperial requirement as a telegraphic service entirely under British control, connecting Great Britain with British North America and our Australasian Colonies, still continues to be practically ignored and neglected, notwithstanding the prominence and importance assigned to it in the deliberations of the Imperial Conference held in London in 1887. Is it not something in the nature of a national humiliation that the first section of a cable from Australia to America—Queensland to New Caledonia—should have been just completed by a French company subsidised by the French Government and the Governments of two of our own Colonies, New South Wales and Queensland? To find ourselves forestalled by a foreign Power in an enterprise that one glance at the map of the world is sufficient to show ought long ere this to have been undertaken by our own Imperial action and resources is a most unwelcome and regrettable experience. Sir George Dibbs, the Prime Minister of New South Wales, is represented in your issue of to-day as defending the alliance of his colony with this foreign enterprise on the ground that it will bring business to the Australian land lines. No doubt it will; but is it wise, patriotic, or statesmanlike on the part of an Australian Premier to materially assist in the strengthening of a foreign foothold in Australian waters? Sir George thinks that the frequent escapes of French prisoners from New Caledonia to the shores of Australia will be checkmated by this new cable service. As there are good grounds for believing that these repeated escapes are too often connived at by the New Caledonian authorities, I do not think Sir George will find many to share his sanguine anticipations in this respect. He also hopes that the construction of this foreign cable will stir up the Imperial Parliament to the necessity of establishing without further delay a new cable service across the Pacific entirely under British control. But will it? I believe that we shall one day have to pay dearly for our apathy in this important matter; and that the time will come when overpowering reasons of Imperial policy will compel us to acquire this foreign cable service at a price that will be enormous in comparison with what it would have cost to construct a Pacific cable at our own expense during the years that we have been idle while our foreign competitors have been at work.—Sincerely yours,

October 17th. J. F. HOGAN

SPARKING DISTANCES IN PARAFFIN.*

BY DR. V. MONTI.

The results obtained by A. Macfarlane in 1877, when investigating the difference of potential necessary to pierce a layer of paraffin of given thickness, are criticised by Dr. Monti in the Paper before us. Dr. Macfarlane had found that for a thickness of 3mm. a difference of potential of 39,000 volts was sufficient. This is about double that required for air, and far below the values obtained by C. P. Steinmetz and by Dr. Monti himself.

The paraffin used by the latter liquefied at 54·76deg. The terminals were brass balls of 3mm., 5mm. or 8mm. diameter. Two balls of the same diameter were mounted inside a glass tube 25mm. thick and 10cm. long. Their distances apart were measured by means of a microscope fitted with an eye-piece micrometer. After that the paraffin was brought to a temperature a little above its fusing point, and allowed to solidify in a partial vacuum of 100mm. It was then fused again, and allowed to solidify in air. In this manner the formation of air bubbles between the terminals was avoided.

The method employed for determining the necessary difference of potential was that of equivalent sparks, in which the thickness of paraffin pierced was compared with the corresponding thickness of air. As the result of all the series of measurements, it may be said that to discharge across a layer of paraffin 1mm. thick, between knobs 5mm. in diameter, requires a difference of potential of 155,000 volts. According to Freyberg, the corresponding difference of potential for air under the same circumstances is 5,050 volts.

Dr. Monti explains the difference between Macfarlane's results and his own by the probable presence of air bubbles in the paraffin in the former case. It would, in fact, be well-nigh impossible to avoid them when allowing the paraffin to solidify between two walls 3mm. apart.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October* 6, 1893.

American Institute of Electrical Engineers.—The subject of local meetings of the American Institute of Electrical Engineers is now being discussed, and it is probable that some action will be taken in the near future. A plan viewed with favour is to have advance copies of the Institute Papers sent to several localities where there is a considerable membership, to be read and discussed there as at present before the main body of the Institute. Adjunct members, or *auditeurs*, not regular members of the Institute, will be permitted to be present at the local meetings and take part in the discussion; the discussion will then be edited by a local secretary, and forwarded to the author and be again edited by the Central Editing Committee before being admitted to the *Transactions*.

Prof. Von Helmholtz.—Prof. Von Helmholtz during his recent short visit received quite an ovation from the scientific circles of New York. A reception was tendered to him at Columbia College to which eminent men in all branches of science and public life were invited, and Prof. A. Graham Bell personally gave him an introduction to the recent achievements in telephony at the rooms of the Long-Distance Telephone Company.

CORRESPONDENCE.

WHAT ARE THE ADVANTAGES OF LOW FREQUENCY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There may be others of your readers beside myself who are anxious to learn, but have difficulty in reconciling, the various statements that are made on the same subject. May I give an example in the hope of explanations ensuing. I observe in the course of a laudatory notice of the central station recently started at Derby that the rate of alternation adopted is 40 periods, and on seeking information from an authority I gathered that the only advantage in this low rate of alternation is that at present alternating motors run better on, or are more easily built for, a circuit of a low rate of alternation, but that otherwise, the plant is more expensive and less efficient. I also noticed in the report of a congress at Chicago that it was stated that "arcs are blotted out at from 40 to 50 periods," and that flickering can be detected in incandescent lamps at low rates; another speaker added that 35 to 37 periods was the practical limit, which seems somewhat adjacent to 40. Perhaps someone who knows will kindly explain whether the station will work inefficiently, or whether the speakers are wrong.—Yours, &c.,

London, October 17, 1893. T. M. W. W.

[Our correspondent evidently refers to some other account of the Derby station than the brief notice in our last issue. The information he has gathered is, we believe, quite correct. In connection with arc lighting on low frequencies, the flicker at Paddington Station, which when once noticed is very irritating, is due to the low frequency employed.—Ed. *E.*]

CARDIFF ELECTRIC LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We beg to hand you copy of a letter, which we have addressed to the Borough Engineer of Cardiff, and which we think of sufficient general interest to bring under your notice.—Yours, &c., CALLENDER'S BITUMEN, TELEGRAPH AND WATERPROOF COMPANY (LTD.),

S. C. LAMBERT, Secretary.

101, Leadenhall-street, London, E.C., October 18, 1893.

101, Leadenhall-street, E.C., London,
October 16, 1893.

DEAR SIR: We beg to confirm the telegram sent you to-day as follows:—"Notice of your Corporation requiring tenders for cables only published in Friday's electrical papers. Tenders required to be sent in to-day, time manifestly too short. Will you grant extension? Please telegraph reply;" and have received your reply:—"Extension of time for receipt of tenders impossible."

Under these circumstances, we desire to lodge a formal protest against the method of inviting tenders which you have adopted, and the totally insufficient time which has been given to independent contractors to make their calculations and to prepare the necessary offers.

We have made inquiries, and find that your Corporation has not advertised in any of the Papers devoted to electric lighting, the notice to which reference is made in our telegram to you being taken from the Press outside the electric industry. We call your attention to the fact that this is the first contract for electric cables "advertised" by a Corporation, which has not been fully announced in the trade journals. The method you have adopted in inviting tenders precludes open tendering by independent manufacturers.

If your Corporation had decided to invite certain makers to a private competition we would have had nothing to say, but we distinctly protest against action such as has been adopted in the case of Cardiff being considered as a public invitation to tender.

We reserve to ourselves the right to make this letter public.—Yours faithfully, CALLENDER'S BITUMEN, TELEGRAPH AND WATERPROOF COMPANY (LIMITED),

T. O. CALLENDER, Manager.

W. Harpur, Esq., Borough Engineer, Town Hall, Cardiff.

[In answer to inquiries, we are informed from Cardiff that the announcement was sent to a London journal; but any similar unpleasantness would in future be easily avoided by the authorities at Cardiff adopting the usual course of selecting the established trade organs for such Advertisements. Our Correspondent's complaint cannot, under the circumstances, be considered unreasonable.—ED. *E.*]

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

TENDERS INVITED.—The Gas and Lighting Committee of the Bolton Corporation invite tenders for the supply and erection of switchboards, accumulators, connections, &c. Specifications, &c., can be obtained from Mr. J. H. Rider, the borough electrical engineer, and tenders must reach Mr. Alderman Miles, chairman of the above committee, at the Gas Office, Bolton, not later than Saturday, November 18th. Further particulars appear in our advertisement columns.

——— The Corporation of Sunderland invite tenders for the supply, in connection with their scheme of electric lighting, of (1) boilers; (2) engines, dynamos, pumps, steam pipes, &c.; (3) motor alternators, switchboard, &c.; (4) main switchboard, instruments, and connections; (5) batteries; (6) insulated cables, &c.; (7) supplying and laying culverts, &c.; (8) copper strip; and (9) gun-metal grip boxes. Persons or firms wishing to tender for any of the above contracts must send their names and addresses to the Borough Engineer, Town Hall, Sunderland, from whom drawings, specification, and forms of tender are to be obtained. Tenders must be addressed to the Chairman of the Highways Committee, and be sent in to the Town Clerk's Office, Sunderland, on or before Friday, November 3rd. Further particulars appear in our advertisement columns.

IMPROVER WANTED.—The Corporation of Hull notify in our advertisement columns that they are prepared to take an improver into their electric light works for a period of two years. Applications must reach Mr. Alfred H. Gibbings, the borough electrical engineer, by 10 a.m on Thursday, November 2nd.

CHANGE OF ADDRESS.—Messrs. Woodhouse and Rawson United (Limited) inform us that on and after November 11th the address of their Glasgow branch will be 12, West Campbell-street, where they are moving to larger and more convenient premises.

LIQUIDATIONS.—It is announced that Mr. Stewart Bogle, A.C.A., of Copthall-avenue, E.C., has been appointed liquidator of the London Metallurgical Company (Limited).

BANKRUPTCY.—Notice is given that Mr. Gourlay, C.A., of 24, George-square, Glasgow, has been elected trustee on the sequestrated estate of Messrs. J. and W. Weems, of Johnstone, Scotland, and of Mr. Alexander Wylie, of the same address, sole partner. The examination of the bankrupt will take place in the Sheriff Court House, Paisley, on Wednesday, 25th inst., at 12 noon; and the second general meeting of creditors will be held at the chambers of Messrs. Thomson, Jackson, Gourlay and Taylor, 24, George-square, Glasgow, on Friday, November 3rd, at 11 o'clock. Creditors to be entitled to the first dividends must lodge their oaths and grounds of debt on or before January 28th next with Mr. J. Gourlay, the trustee. Affidavits already lodged do not require to be repeated.

PRESENTATION.—The recent marriage of Mr. Rashleigh Phipps was on Friday last made the occasion by the employés of Messrs. Rashleigh Phipps and Co. for the presentation of a handsome marble clock and an illuminated address, which was followed on Wednesday last by a dinner to the employés under the presidency of Mr. Snowdon, the general foreman.

THE FOWLER-WARING CABLES COMPANY (LIMITED).—This Company is now represented by Mr. Alfred E. Garbutt in the north of England; by Mr. J. Vincent Swindells in Manchester and Midlands district; and by Mr. Charles Parker in the Eastern and South-Eastern districts, including London. Offices will shortly be opened in Newcastle as the centre of the Northern district, and in Manchester as that of the Manchester and Midlands district.

A T-SQUARE ATTACHMENT.—Mr. J. P. Maginnis, the inventor of numerous drawing instruments and appliances, is introducing an attachment for an ordinary T-square, which gives all the advantages of a movable head. One use of such a square is in making additions to a drawing. The drawing may be pinned down to a board without reference to the T-square; and a correct adjustment may be immediately obtained.

THE "HARD" INCANDESCENT LAMP.—Messrs. Wilhelm and Co., of 132, Wool-exchange, E.C., notify us that they have been appointed representatives in this country of the "Hard" Incandescence Lamp Company, of Zürich, and are prepared to supply the lamps manufactured by that firm after November 10th next. Messrs. Wilhelm and Co. issue printed particulars concerning the Hard lamps, which can be obtained on application. They are intended for "3½ watts per candle, and a mean duration of 800 to 1,000 hours."

Digitized by Google

STORAGE BATTERY PATENTS ABROAD.—Judgment was pronounced on Wednesday at Frankfort-on-the-Main against the plaintiffs in the action brought by the Electrical Power Storage Company (London) against the Pollak Company, the proprietors of the accumulator works in that city, to restrain the latter from manufacturing or selling accumulators. This is the first time that a German court of law has given a different decision from that pronounced in similar actions against other accumulator manufacturers preferred by the actual patentee—the Accumulator Manufacturing Company of Hagen.

HARD FIBRE.—We have received samples of the Delaware Hard Fibre Company's manufactures from their agent, Mr. J. Burns, 15, Long-lane, E.C. In addition to use for pump valves and other mechanical purposes, for which it appears to be excellently suited, it is claimed that this material is an insulator of electricity. We have examined the samples, which closely resemble ordinary red vulcanised fibre, and find that, like that material, so long as it is quite dry, the insulation of the hard fibre is good, but falls off in the presence of moisture, which is readily absorbed.

MESSRS. SIEMENS BROS. AND CO.—We have received from this firm a copy of a new price list just issued of Siemens dynamos, which contains illustrated particulars of the various types of machines manufactured by Messrs. Siemens Bros. Included in the list are a number of carefully compiled tables, from which full information can be gathered respecting output, weight, dimensions, prices, &c. The information given as to the actual cost of machines and spare parts is very complete.——Messrs. Siemens Bros. also announce that on and after November 10th they will be prepared to supply the Siemens and Halske incandescent lamp in this country.

MESSRS. NALDER BROS. AND CO.'S PRICE LIST.—We have received a very complete and admirably illustrated price list of the electrical testing, mathematical, optical, and other instruments made by this firm. Among the new apparatus in this, the fifth edition of the catalogue, we find a large variety of standard cells, among which the Carhart-Clark cell is recommended, Messrs. Nalder Bros. and Co. are the sole makers in Europe. The Carhart modification of the Helmholtz cell gives 1 volt with a temperature coefficient of only 0·009 per cent. per degree centigrade. New electrometers and galvanometers are illustrated, including Dr. Lodge's pattern for physiological work. For small alternating currents a torsion galvanometer is made. Prof. Anthony's form of Wheatstone bridge is included, and among a variety of large resistances we find coils of 100 ohms to carry one ampere, manganin standards of the Reichsanstalt pattern, and potentiometers. Messrs. Nalder's new optical department and the extensometers, cathetometers and clocks, appear to fully maintain the high standard of their electrical apparatus. The list is provided with a useful telegraphic code.

BARROW.—At the meeting of the Town Council last week it was decided to apply for a Provisional Order empowering them to supply electricity within the borough.

BECKENHAM.—The Local Board have approved the conditions under which the Crystal Palace Electric Lighting Order is to be carried out in their district.

BELFAST.—An order of the Privy Council prohibits the inspection of cattle at the harbour after sunset, but an agitation has been started to have an electrically-lighted depôt where such inspection may take place, so as to do away with the present delay and inconvenience.

BIRKENHEAD.—Some months ago the Town Council appointed a sub-committee to consider the best means of carrying out the provisions of their Electric Lighting Order, and Mr. Shoolbred and Dr. J. Hopkinson were requested to report thereon. These gentlemen have now presented their reports, and they state that, whilst no great difficulty would be met with in doing the work, the straggling character of the district would render the cost rather considerable, the estimates ranging, according to the scheme proposed, from £15,000 to £40,000. The sub-committee think it advisable to have personal interviews with Mr. Shoolbred and Dr. Hopkinson, and the whole question will shortly be considered by the Corporation.

BOLTON.—The Local Government Board have given their sanction to the loan of £40,000 in connection with the supply of electricity, and have given consent for the Corporation proceeding with the erection of the works.

BRADFORD.—The Gas and Electricity Supply Committee of the Town Council have had under consideration the desirability of lowering the charges for electric current used for motors during the day-time, and a sub-committee was appointed to deal with the subject.

BUXTON.—Some time ago the Local Board appointed an Electric Light Committee to inquire generally into the subject of lighting the town, and inquiries were made at the last meeting as to when they are likely to report.

CARRIAGE LIGHTING.—The Sherborne Electric Installation Company, of Sherborne, Dorset, are charging accumulators for the lighting of carriages and other vehicles made by Messrs. Hill and Ball, a well-known firm of carriage builders at Sherborne.

CHESTER.—There was an animated discussion at the meeting of the Town Council last week with reference to a recommendation of the Watch Committee that the Hop Pole Paddock be selected as the site of the central electric station. Notwithstanding the telegraphed opposition of the Duke of Westminster, the Town Council decided by a large majority to adopt the site.

DEWSBURY.—The Board of Guardians, at their meeting on Friday, resolved to give their Electric Lighting Committee power to consult an electrical engineer in respect to the scheme suggested for lighting the new infirmary and the workhouse. The estimated cost is about £2,100.

DOUGLAS (ISLE OF MAN).—The Town Commissioners have received from Mr. G. T. Pardoe, of Manchester, two approximate estimates of the cost for hydraulic electric light stations; but it was stated at a recent meeting of the Commissioners that the Health Committee had under consideration a scheme for the better lighting of the town, and it was decided that meanwhile they could not deal with Mr. Pardoe's offers.

EALING.—It is feared that the works in connection with the installation of the electric light will be somewhat delayed, in consequence of no official inquiry having yet been held by the Local Government Board into the application made by the Local Board for sanction to borrow the amount (£25,000) required for the purpose of the scheme. The Local Government Board have intimated that the inquiry will be held as soon as the engagements of the Inspectors permit.

ELECTRICITY IN LAUNDRY WORK.—At Exwick, Devonshire, some large premises formerly used as flour mills have been taken over by a steam laundry company. The machinery is driven by the old mill waterwheel, which also drives the 80-light dynamo which lights the whole building with electricity. Electrically-heated irons, including a Mirror collar ironer, are used.

ELECTRIC TANNING.—Mr. L. A. Groth has introduced his electric tanning system at Orbe, near Lausanne, with success. He informs us that the largest tanyard in this place is being reconstructed according to the "Groth" system.

THE ELECTRIC LIGHT IN MILLS.—One of the largest electric light installations for corn mills is being fitted up at the Mersey Rice and Flour Mill at Liverpool. The installation comprises two 400-light dynamos and storage for 400 lights, together with a separate engine and dynamo for lighting the mill in the day-time.

FRANKFORT-ON-THE-MAIN.—The Municipality have adopted a proposal of the Executive Department for the erection of a central electric light station. The installation will be according to the plans submitted by Messrs. Miller and Lindley, and will be on the alternate-current system with transformers, and a low-pressure distribution. The dynamos will be constructed by Messrs. Brown, Boveri and Co., of Baden, Switzerland, and the cables will be supplied by Messrs. Felten and Guillaume, of Cologne.

GALASHIELS.—The Town Council, at their last meeting, had under consideration a request of the Caledonian Electric Supply Company for consent to apply for a Provisional Order to supply electric light in the burgh, but after a lengthy discussion a decision was adjourned to a special meeting, at which the subject could be more fully explained.

GLASGOW.—With respect to the Trade Note last week under this heading, Mr. Arnot requests us to state that the report he is preparing is not on electric haulage, but on the lighting of the tramcars.

GRIMSBY.—The Lighting Committee of the Corporation have decided to recommend the Council to apply for a Provisional Order, and meanwhile have appointed a sub-committee to take charge of the matter.

THE GUILDHALL.—The City Lands Committee recommend the City of London Corporation to extend the electric lighting to the art gallery at an estimated cost of £290.

HALIFAX.—The electric lighting of Halifax is at present provided by a private company, but as the Corporation some time ago decided to take in hand the question of electric lighting for the town, the local company have decided to stop business on the 18th of next month. A deputation of tradesmen last week waited upon the Electric Lighting Committee of the Corporation requesting them to make arrangements to continue the supply until the Corporation works are ready. The Committee, however, were unable to give a favourable answer to the request, and it seems likely that those tradesmen who have the electric light fitted up will have to fall back on gas in the interval. We understand that the Electric Lighting Committee are in negotiation for the purchase of a site for the central station.

HEREFORD.—At the last meeting of the Herefordshire County Council the County Surveyor reported that he had gone into the

Digitized by Google

matter of the proposed lighting of the Shire Hall by electricity, and he found that owing to no facilities existing for obtaining the requisite motive power at a reasonable cost, the capital expenditure for providing such power, with the necessary cables, wires, dynamos, lamps, &c., would be so great that he could not offer any recommendation. The report was adopted.

HEYWOOD.—Consent has been given by the Local Government Board to the Corporation borrowing £3,500 for machinery and electric lighting at the sewage works, to be repaid in ten years.

KILLARNEY.—The electric light or gas lighting for the town was the question on which the recent municipal election was fought, and in the result the advocates of the newer illuminant were successful, which we hope will terminate the deadlock that has occurred with regard to the lighting question.

LEEDS.—The Highways Committee of the Corporation last week decided to renew the lease of the Thomson-Houston Company's overhead electric tramways to Roundhay Park for six months, after which time the lease will be renewed for periods of one month at a time, until some final arrangements be arrived at.

NEWPORT (MON.).—The Town Council at their last meeting had under consideration the preliminary report of Mr. Hammond upon the proposed electric light installation. The site suggested for a central station is in Friars Fields, and the estimated expenditure, including the mains, is £25,000. The Council empowered the Sub-Committee to request Mr. Hammond to proceed with the preparation of the detailed plans and specifications, in order that tenders may be obtained at the earliest possible date. It was also decided to apply to the Local Government Board for permission to borrow the amount required for an electric light installation.

PAIGNTON.—It was stated, at the last meeting of the Local Board, that further offers had been received from firms for the electric lighting of the town, and it was resolved to appoint a special committee to consider the whole subject and report.

PLYMOUTH.—The Corporation have decided to apply for a Provisional Order authorising them to supply electricity within the borough.

PORTSMOUTH.—Everything is progressing favourably with the electric light installation, and Alderman Ellis and the Committee hope to have it complete by Christmas. The work of laying the mains beneath the streets and pavements is proceeding with rapidity, and in the course of a few days the cables will have been drawn through the conduits.

ST. PANCRAS.—The West St. Pancras Ratepayers' Association have passed a resolution to the effect that, while heartily approving of the electric light, they were desirous of impressing upon the Vestry the necessity of improving the lighting in the upper part of Park-street. One of the speakers said that the light was not nearly so good as the superseded gas light.

SHANGHAI.—The plant and business of the New Shanghai Electric Company (Limited) were acquired by the Shanghai Municipal Council on September 1st last. The Electrical Department has been placed in charge of Mr. Charles Mayne, the municipal engineer.

SHOREDITCH.—At the last meeting of the Vestry a report was brought up from the Electric Lighting Committee, stating that they had considered the reference back to them of their report of the Pitfield-street site, with instruction to make a further financial statement and report. So far as the electric lighting scheme was concerned, they considered the report of Mr. Manville contained the fullest financial information that could be afforded until a site had been actually acquired. With regard, however, to the dust utilisation part of the scheme, and the amount of heat which would be available for baths and washhouses and motive power, the Committee thought it would be advisable and very useful in a scheme of this magnitude to obtain a financial report from Messrs. Manlove, Alliott and Co. The Committee had accordingly instructed them to report what results they could guarantee with regard to the cost of burning 20,000 tons of dust per annum, and the amount of heat which would be available for baths and washhouses and electric lighting purposes, and the capital cost of maintenance, for the sum of £10. 10s. The Vestry approved the action of the Committee.——Mr. W. T. Baker, of 25, Wormwood-street, has forwarded to the Vestry plans of a new scheme for the erection of baths, electric lighting station, and dust destructor, which have been sent to the Electric Lighting Committee and the Baths and Washhouses Commissioners. Mr. Baker claims that his scheme would be self-supporting.

SOUTHEND.—The Corporation have empowered the Highways and Works Committee to invite offers for the undertaking and carrying out of the Corporation's Electric Lighting Order.

TAUNTON.—The Town Council have decided to purchase for the central station an additional boiler from Messrs. Davey, Paxman and Co., at a cost of £380, and a steam drum from the Babcock-Wilcox Company (Limited), at a cost of £30.

WARMINSTER.—The Local Board have had several communications from electricians in London in reference to the question of lighting the town by electricity, and the matter is now being considered.

WESTON-SUPER-MARE.—A sub-committee of the Town Commissioners has been appointed to consider the subject of lighting the town by electricity.

WINDSOR.—Councillor Dyson had given notice of his intention to move at the last meeting of the Town Council—"That this Council request the Board of Trade to revoke the Provisional Order granted to the Windsor and District Electric Lighting Company; that the Council do apply to the Board of Trade for a Provisional Order for Windsor and Eton, and that a Committee be formed, to be called the Electric Lighting Committee, to consider the whole question, and to report from time to time to the Council on the subject," but when called upon to move the resolution, he said that since he gave notice certain questions had sprung up which seemed to alter the phase of the whole thing; and he asked permission for the motion to stand over, which was agreed to.

WOOLWICH.—The Local Board of Health have requested the Lighting Committee to consider and report on the expediency of lighting Beresford-square with the electric light. The Baths Commissioners are considering the propriety of so lighting the public baths.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—The Specifications of Applications for Patents are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions, or where complete specification accompanies application an asterisk is suffixed.

COMPANIES' MEETINGS.

Brazilian Submarine Telegraph Company (Limited)

The fortieth ordinary general meeting of the shareholders of this Company was held at Winchester House, Old Broad-street, on Wednesday last, under the presidency of Sir John Pender, G.C.M.G., M.P.

The SECRETARY (Mr. Richard Collett) having read the notice convening the meeting, and the minutes of the previous ordinary general meeting, and the report of the Directors having been taken as read,

The CHAIRMAN said: Ladies and gentlemen, before beginning the business of this meeting, I may say that a name has just been mentioned (by the Secretary, in reading the minutes of the last general meeting) which has been long associated with this Company—that of Sir James Anderson. I was in the room at the last half-yearly meeting, when Mr. St. John Brodrick made his statement. At that time Sir James Anderson was lying in a very serious state, and since then he has passed away. We all deeply regret the loss of a very valued colleague, who was long associated with this Company—indeed, from its inception—and whose name will always be associated with the progress of submarine telegraphy. The world moves on, men pass away, but still the work of the world has to be done. As regards our Company, the work is being done. Probably my long association with submarine telegraphy is the reason why I am occupying this chair to-day. As you know, I have a fair amount of work to do, but telegraphy is probably an exception to almost every other business. It is one great chain, and every cable is directly or indirectly connected with the chain, forming a link in it, and, therefore, it is, above all systems of business, one which requires at its head somebody who may, more or less, have his eye on every link of that chain. The Brazilian Submarine Telegraph Company is one of those links—a very important link—and it has been a very successful link in the chain of submarine telegraphy. It has troubles to pass through at times when there is revolution here and there and almost everywhere; and while our system is principally connected with those places we have to keep a watchful eye over it, and to see that the system is kept up, and, to speak very plainly, that the dividends do not go down. I think we are probably in that position to-day. It is a position of some anxiety, but we have perfect confidence in the work which we have to do, in the value of that work, and in its importance in connection with political, social, commercial, and every other progress, for, more or less, this system is identified with such progress. In taking the chair of this important Company, in addition to those I already hold, I am simply taking the chair of another link, of another system, which, so far as we are concerned, has been a system successful alike to the public who use it and beneficial to the shareholders who are interested in it. Now, gentlemen, after those remarks—which, perhaps, I must almost ask your pardon for having made—I would say that all those who have taken part in this great industry, which has more or less revolutionised the world, are entitled to have the fullest information about it. You are also to be congratulated on the success which has attended your investment. I will now deal with the accounts of the last six months. The receipts for the half-year ended June 30, 1893, were £106,860, and for the previous half-year they were £113,892, showing a decrease of £7,032. As compared with the income of the corresponding half-year of 1892—namely, £111,870, the decrease is £5,010. The message receipts show a decrease of £7,290, while the miscellaneous receipts from interest, rents, and transfer fees result in an increase of £258, leaving the net decrease at £7,032. In the half-year under review we carried about 3,500 more messages with South America than in the previous six months, yet we realised about £7,290 less. This results from two causes—first, a reduction in the tariff of charges from April 1st last; and, secondly, a further reduction in the exchange value of the Brazilian silver currency, the value of the milreis having averaged in the half-year 12⅛d. as against 13⅜d. in the previous half-year. On the other hand, there are increases in the receipts from the traffic with the African Coast and Cape Colonies, transmitting through our St. Vincent station, of £500 and £130 respectively. The total expenditure for the half-year was £40,580, which, compared with that of the previous six months—namely, £24,536—shows an increase of £16,044. This very large increase results from quite an exceptional state of things. As reported at the meeting in May last, there had been several repairs of cables made, and the cost thereof appears in the accounts now before you. These operations included the renewal of all our shore ends at Madeira, four in number, with specially designed heavily armoured cable to resist the constant wear and tear resulting from the action of the tides and storms breaking on the rough beach where our cables land. There was also a repair of our first cable between Maderia and St. Vincent, in deep water, and of both cables between St. Vincent and Pernambuco, one near St. Vincent and one near Pernambuco. The cost of these operations, including the conveyance of spare cable to Maderia and St. Vincent, was £19,557. Now that is a large sum, but you must bear in mind in connection with submarine telegraphy that if you put new cable in you are strengthening your system generally. These repeated repairs usually result in a considerable addition of new cable, and that means a prolongation of the "life" of the original cable. I mention that in order to impress upon you that while we are expending largely, we are also prolonging the "life" of the cable itself. Of course, submarine cables do not last for ever, but if we are effecting repairs from time to time and introducing new cable where the original has become weak through some action which it is very difficult to comprehend, when the portion which has suffered by friction or by other causes—perhaps chemical causes at the bottom of the sea—has been removed, we are strengthening the system as a whole, and therefore while I have to mention this very large expenditure, for it is a considerable sum, I assure you that your cable is always stronger for it. The item of agencies shows an increase of £1,115, arising from prolonged negotiations with the Brazilian Government upon special matters, and from the employment of additional agencies upon the Continent. The other principal increases are in rent and taxes, &c., arising from the more energetic collection of taxes in Portugal and St. Vincent, £175; in maintenance of land lines and electrical expenses, £638, of which £344 is in respect of the cost of arranging for the duplex of No. 2 cable being adapted for application to No. 1 cable when wanted, and £294 is due to the renewal of land lines at Madeira and Pernambuco. There is a particular point which I should like to call your attention to in connection with this question of the duplexing of cables. This enables a cable which has cost a very large sum of money to carry telegrams both ways. It is an invention which has doubled the carrying capacity of submarine cables, although it has not doubled their value. It has, however, doubled their carrying capacity, and it is very doubtful whether we could to-day do the amount of work we have to get through without expending more money on the cables if it were not for this clever system of duplexing. This Company did not avail itself of this system in the early days, because, probably, it was not required, but latterly they had the advantage of all this duplication on the lowest possible terms, because before they adopted it the patents had practically expired, and there was not in your case that heavy payment for the duplexing which the other companies had to make. We are therefore now in the enjoyment of this large additional carrying power, and we have not paid the high price which many of the other companies paid for it. This is probably a matter of congratulation for us, although it is not so much so for the inventors. Legal and other professional advice upon special matters amounted to £318. The extension of the offices and quarters at St. Vincent, and the providing of tanks for the storage of spare cable having been completed, there is a reduction of expenditure on those heads in this half-year of £5,713. Other increases and decreases of smaller moment being giving effect to, the result is, as above stated, an increase in expenditure of £16,044, mostly due to the unusual number of repairs of cable falling upon us in the June half-year. In the present half-year, now more than half expired, we have so far, fortunately, had no expenditure for repairs. Therefore, having made these ample repairs, we are now in a position, I hope, to go for a period without incurring any further expense. Notwithstanding all this outlay, however, in the past half-year, we are paying you the same dividend, although we are not adding to the reserve fund in the same degree that we have hitherto done. Probably, with the large sum we have now got in reserve, it is not so necessary to make these additions, but I would mention to you that if we are to hold our own, if we are to look forward to the continuance of the prosperity which has so far been enjoyed by the Company, you must not grudge, but rather encourage, the increase of our reserve fund. I think that, after all, the reserve fund is the backbone of our system. There is an old saying that "You cannot have your cake and eat it too," but by having a reserve fund the value of your property is immensely added to, and the security of your dividend is greatly strengthened. I would, therefore, giving you my view of the matter, say that the reserve fund is one of the greatest and strongest factors which you can have in the submarine telegraph system. There are several things affecting your interests floating in the air just now. We have still in existence a revolution in Rio, and we have had something very nearly akin to it in the Argentine. It is, however, a very curious and very important factor for you to understand in regard to submarine telegraphy that revolutions, the disturbing effects of which throw privations on people, generally have somehow or other to find voice in the submarine telegraphs, and the consequence is that if times are very good, submarine telegraphy more or less benefits, while if times are very bad we do not benefit to the same extent, though we do not die out. Submarine telegraphs are used in times of hardship and privation, just the same as they are used in good and prosperous times, although, probably, not to the same extent. I hope that better times are dawning upon those countries where revolution has been so rampant lately. There is no doubt at all that it would be better for those countries if that were the case, and much more satisfacfactory for their commercial interests generally, and as we claim commerce to be our first factor, I think we may hope and wish that a more prosperous commercial state of things will soon prevail, both in the Argentine and in Brazil. In the last year or two you have had brought before you the subject of the competition that was likely to arise. In this system of telegraphs, I do not believe, as I have said on former occasions, that opposition or competition is as advantageous as many people say that competition as a rule is, for this reason—that the Submarine Telegraph Cables form a peculiar and isolated system. It is a system that requires great attention, great care, and it is a system which, more or less, dies out unless it is maintained in thorough efficiency. The amount of work that a cable can do is large, and where you put down two instruments to do the same work, of course you lessen the monetary value of the service; and what I have held, and what I hold now, in the systems over which I am more immediately presiding, is that competition is not advantageous, but we have endeavoured to show that we conduct that system on the broadest principles—principles in connection with which it must be acknowledged by everyone that, while we have the power to squeeze, we have and we exercise the power to open our hand and do generous things. That is our policy, and I think our shareholders have generally endorsed it. We have done many things with regard to our staff. They have certainly benefited by the progress and prosperity of this system, and we have laid down a scheme which some of the wisest statesmen have endeavoured to lay down, namely, to provide for our people in their later years. All these things we are bearing in mind. We are conducting what I freely admit to you I should like to call a monopoly, but a monopoly based on such principles that all who participate in the working of it ought to be satisfied that it is carried on on broad and generous principles. I think I have pretty well mentioned all the points that I had to bring

Digitized by Google

before you, but there is one of some importance to which I have yet to allude. You will have observed in the papers lately that telegraphic communication has been established between Lisbon and the Azores. This Company, the Eastern Company, and the Telegraph Construction Company have all taken a part in carrying out that work. We did it for two reasons. We believe it is a system that may be eventually worked into a profitable and valuable one, and we also got a very valuable *pro quo*. We have got an extension for ten years of exclusive privileges, which are very valuable indeed, from the Portuguese Government. The Eastern Company has got the same privileges, and the advantage to us is probably more important and more valuable than I am prepared to put before you in figures. At all events, this Company will now have one-third interest in that Azores system, and they could not have spent their money in a better way to secure something like permanency for the next ten years to their system connected with the general system. That is an important advantage. The competition which we have to contend with I do not attach very serious importance to. I think that those who are dealing with that competition have realised the important fact that it does not pay, and any concern that does not pay does not live healthily, to say the least of it. I therefore think we may see important changes in that direction. In the meantime, I am quite certain they find that the reduction of rates does not add to their exchequer. I am speaking of the South American Company, which has been lately established, which has often been talked about here, and I think we have got this matter fairly in hand. We will treat it liberally, and in such a way that I hope common sense will prevail, but they will probably find that they will be better without this competition than with it. We have another competition, and that is by an American company—what is called the Galveston or Central American Company. That is competition which we of course recognise, and if it comes to a reduction of rates it can do a very great deal of harm; but the American, as a rule, does not lay down any system for the purpose of losing money by it, and as we know that their object is to get money out of it if they can, we shall take care that they only get money from it on principles that will be fair and just to us. We have a great banking. I think, united, our system is the biggest in the world, and they will find that in dealing with us there must be something like fair play and something like a *quid pro quo* to be given for anything they get. I have thought it necessary, perhaps, to say a little more to-day than I should do generally, and I think I have given you pretty full information upon all that is going on in connection with your enterprise. There is one other point I may refer to which is personal to the Board. For a great many years—over 20 years now—you have had a very successful and very good company altogether, and I do not think, from my point of view, that the gentlemen who sit on this side of the table have been unduly paid. We are going to make a little alteration in that respect which will lead to an expenditure of about £300 more upon the Board, and I may tell you—and I think it is well to tell you—that that £300 will come into my pocket principally. In other words, that will be an addition to the money you already pay to the Directors, but it will be in the form of salary to the Managing Director. He will cease to draw his fees as Director, and this additional sum that I have mentioned will be drawn from the Company's exchequer. We are not bound by the Articles of Association to put all this before the shareholders, but I am quite certain that looking to the honest services which you have had for 20 years from this Board, and looking at the large reserve fund you have accumulated, a little further consideration is due to the Directors on the part of the shareholders. I will now move—

"*That the report of the Directors and the accounts to June 30, 1893, now submitted, be approved and adopted, and that a dividend be now declared of 3s. per share, making with the interim dividends already paid, a total dividend of 6 per cent. for the year, and also a bonus of 1s. per share, making in the aggregate a distribution of 6½ per cent. in respect of the profits for the year ended June 30, 1893, the said dividend and bonus to be, respectively, free of income-tax.*"

Mr. FREDERICK YOULE: I have much pleasure in seconding the resolution.

The CHAIRMAN then invited discussion, but no shareholder rising to address the meeting, he put the resolution in the usual way, and declared it carried unanimously.

On the motion of the CHAIRMAN, seconded by Sir HENRY D. GOOCH, Bart., Mr. J. Denison Pender was re-elected to his seat at the Board, as was also Mr. Frederick Youle, on the motion of the CHAIRMAN, seconded by the Hon. W. ST. JOHN BRODRICK, M.P.

Mr. E. B. LIDDELL afterwards proposed, and Mr. GEORGE DUNCAN seconded, the following resolution:—

"*That the firms of Messrs. Deloitte, Dever, Griffiths and Co. and Messrs. Gane, Jackson and Jeffreys be, and they are, hereby elected auditors to the Company for the ensuing year at the remuneration of £50 to each firm.*"

The CHAIRMAN stated that up to the present time the accounts of the Company had been audited by individual members of the firms mentioned in the resolution, but it was now thought better that the audit should be in the hands of the firms named, which consisted of chartered accountants. He might state that a regular audit of the accounts of their Company, and of all the companies with which he was connected, was carried on monthly, apart from the special audit, and the shareholders might, therefore, be perfectly satisfied that everything was done straightforwardly and honestly.

Mr. HENRY NUDING inquired whether the investments were taken at cost price, or at their present market value.

The CHAIRMAN replied that they were taken at cost price, and that there was a very considerable margin of profit on them.

Mr. W. GRIFFITH then proposed a vote of thanks to the Chairman and Directors, and, while expressing deep regret at the death of Sir James Anderson, said he thought they were to be congratulated on the appointment of so able a successor as Sir John Pender. He afterwards referred to the strong financial position of the Company.

Mr. NUDING seconded the motion, which was unanimously adopted.

The CHAIRMAN, in reply, referred to his connection with the Company from the outset—from the day on which he met the late Emperor of Brazil in London, when a conversation ensued regarding a cable to His Majesty's country. The enterprise had been successful, and he was greatly interested one way or another in the Company, particularly as Chairman of the Globe Telegraph Trust, which was by far the largest holder of shares in the Brazilian Submarine Telegraph Company. He had at all times kept a watchful eye on the Company, with the object of assisting in protecting its interests. Although, therefore, he had addressed them that day for the first time, it had carried him back to the days when he took an active part in the inception of the Company.

The proceedings then terminated.

NEW COMPANIES, STATUTORY RETURNS, &c.

CORLETT ELECTRICAL ENGINEERING COMPANY (LIMITED).—The 1893 return of this Company shows that 620 shares, out of a nominal capital of £10,000, in shares of £10 each, have been taken up, of which 100 were issued as fully paid. Upon the remaining 520 shares a call of £7 per share has been made, resulting in the payment of £3,640.

DOMESTIC TELEPHONE COMPANY (LIMITED).—The statutory return of this Company, made up to July 28, 1893, has been filed. The nominal capital is £20,000, divided into 3,990 "A," or Ordinary, and 10 "B," or management, shares of £5 each, of which 2,662 "A" and 10 "B" shares have been subscribed for and allotted. Of these, 2,000 "A" and the "B" shares were issued as fully paid to Sir C. S. Forbes, for the sale to the Company of the following patents, viz., an improved telephone combination, No. 10,466, of 1892; an improved switchboard, No. 13,338, of 1892; an improved telephone combination, No. 18,423, of 1891; improvements in telephones, narrow double tympan, No. 9,496, of 1892; improvements in microphones, No. 13,146, of 1893; improved signalling apparatus for telephones, No. 16,877, of 1892; improvements in the arrangement of telephone circuits, and switching devices therefor, No. 20,670, of 1892; and improvements in telephones, No. 3,488, of 1893. Upon seven "A" shares the full amount has been called, and upon the remaining 655 "A" shares a call of £2 per share has been made, resulting in the payment of £315, and leaving no less than £1,030 in arrears.

ELECTRIC LIGHT REGULATING SYNDICATE (LIMITED).—The statutory return of this Company, made up to and filed on August 24, 1893, shows that out of a nominal capital of £1,000, in £1 shares, 865 have been taken up, and the full amount called and paid on 240 of them. The remaining 625 were issued as fully paid to Edward P. Davis and Adrian C. Collins, in consideration for the sale to the Company of their rights to letters patent No. 19,874, of November 4, 1892, for an invention relating to the regulation of the supply of electrical energy and other electrical apparatus.

CITY NOTES, &c.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended October 15th were £849, as against £902 for the corresponding period of last year, being an decrease of £53. The total receipts for the half-year amount to £12,111, against £11,755 in the corresponding period of 1892, being an increase of £356.

IMPERIAL CONTINENTAL GAS ASSOCIATION.—The Directors recommend a dividend of 5 per cent. for the half-year, and a bonus of 1 per cent.

MEDICAL BATTERY COMPANY (LIMITED).—The latest development of the so-called Electropathic Belt is the issue this week of a prospectus inviting subscriptions for 11,000 Six per Cent. Cumulative Preference shares in the Medical Battery Company (Limited), the capital of which Company is (the prospectus states) £200,000, £100,000 of which is (also according to the prospectus) "fully paid." Mr. C. B. Harness is President of the Company, and Dr. Robert Wallace, M.P., "has consented to serve on the Board of Directors in the interests of the Preference shareholders." It is interesting to learn from the prospectus that the business which the Company conducts is the manufacture and sale of all kinds of electrical and mechanical apparatus and instruments for medical and surgical treatment, and that the business has proved highly profitable in the past. The object of the present issue of capital is stated to be the establishment of a residential institution in London, which, it is calculated, will also prove highly remunerative. No reference is made to recent litigation or to its effect upon the business of the Company during the current year, information which might prove instructive to intending applicants for shares. There can, of course, be no connection between the results of this litigation and the necessity for further capital.

NOUVELLE SOCIETE DES TELEPHONES.—The Société Générale des Téléphones and the Menier cable establishments are to be amalgamated under the above title, with a capital of 18,600,000fr.

ST. JAMES' AND PALL MALL ELECTRIC LIGHT COMPANY (LIMITED).—The electric current sold by the Company during the quarter ending September 29th last amounted to £4,820, as against £5,763 for the corresponding period of 1892.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended October 13, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £2,941.

Digitized by Google

WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED).—The Directors, after placing £3,000 to reserve, have decided to recommend the under-mentioned dividends for the six months ended June 30, 1893, viz:—6s. per share on the First and Second Preference shares, and 1s. per share on the Ordinary shares. The traffic receipts for the two weeks ending October 15th were £1,662, as compared with £2,035 for the corresponding period of last year. The June receipts, estimated at £5 016, realised £5,009.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 806.—Vol. XXXI. FRIDAY, OCTOBER 27, 1893. PRICE FOURPENCE.
Annual Subscription (U.K.), 19/6

NOTES.

Nothing has been heard about the certification of meters for some time. On August 15, 1892, a letter was sent from the Board of Trade to the County Council (*The Electrician*, Vol. XXIX., p. 435) saying that the several patterns of meters which had been submitted for approval had been carefully considered, and that though some of the patterns had many merits, and the laboratory tests had been in several particulars satisfactory, no meter had showed such perfection as to justify the conclusion that serious defects might not appear in actual working. Under these circumstances the Board of Trade invited the co-operation of the London County Council in providing for a thorough practical test. Pending this trial, which it was anticipated would occupy a period of about 12 months, no approval of any meter could be given by the Board of Trade. We have made inquiries about these tests, and understand that the County Council have been carrying them out, but have suggested a further extension of time. Their report will probably be communicated to the Board of Trade in the course of next month. A report upon the principles, construction, and results of various meters under scientific tests will probably be made by the Electrical Department to the Board of Trade, but it is not likely that this will be made public. The publication of the general results, however, would be of considerable interest, for although inventors and makers could learn by inquiry the limits of accuracy and other conditions necessary for obtaining a certificate, electrical engineers and others would like to know how far the conditions have been met.

The Paper by Mr. B. A. Dobson on the "Artificial Lighting of Workshops," which was read before the Institution of Mechanical Engineers, and of which a portion will be found in another column, calls attention to a mode of using arc lamps which has been singularly neglected. A Jaspar lamp at the Paris Electrical Exhibition in 1881 was thus used to light one of the upper rooms, with an excellent result. The lamp was inverted and fixed in a stand of flowers in the middle of the room, casting all the light on to a white ceiling. The common idea that a white surface is a poor reflector, giving back only 50 per cent. or so of the light, may, perhaps, account for the general hesitation to copy this method. It has been shown by Dr. Sumpner and others that the reflecting power of a good dead-white surface may exceed 80 per cent. A great advantage of this mode of lighting is that the light comes, not from a point, or from a comparatively small globe, but from a surface of many square feet. Such a surface cannot cast sharp shadows, or, indeed, under most circumstances, any noticeable shadow at all, where several lights are used.

The reflector for an inverted arc lamp should subtend a large solid angle to the arc. An examination of the curve of distribution of light from an arc lamp shows that but little light is emitted at angles greater than 70° with the axis of the carbons. A reflector to catch all the light falling within this limit would subtend a solid angle of $0{\cdot}684\ \pi$, or in plainer language—given the distance of the reflector above the arc, the radius of the reflector should be about three times this distance. Theoretically the solid angle alone need be considered, but practically the reflector should be as large as possible in order to avoid shadows, particularly the shadow of the arc lamp itself.

Mr. Steinmetz writes to us this week to defend the high estimates of the candle-power of search lights which have from time to time been made. We cannot agree with him. There are two ways of measuring candle-power. The ordinary way is direct and assumes that the rays of light are emitted from a point. Having adjusted a photometer at a certain distance from this point, the candle-power is directly as the square of this distance. The other way is not so common, but it must sometimes be used. The illumination of a surface upon which the light falls is measured, and the candle-power is calculated as that which would give the same illumination if emitted from a point at a certain distance. We have already pointed out in connection with a lighthouse at a London exhibition that, as measured photometrically, if the beam is strictly parallel, the candle-power would be indefinitely great, and if the beam were slightly converging, the candle-power would be more than infinite; in fact, the word candle-power ceases then to have any meaning.

But Mr. Steinmetz sins in good company. Dr. J. Hopkinson, at the South Foreland lighthouses in 1884 and 1885, made measurements which purported to give the candle-power of the lights. With due deference to such an authority we venture to suggest that what he did do, and what Mr. Steinmetz has done, is to make a photometric measurement and to take the square of the distance from the light as if it were a radiant point. In practice the beam of a search light is never truly

Digitized by Google

parallel. It consists of a number of nearly parallel rays mixed with diverging and with converging rays. The latter cross the axis, and at a considerable distance the rays may be all considered as diverging. In certain cases a diverging beam is intentionally used. The light then proceeds as if from a point at a considerable distance behind the projector. The value of a search light may be estimated in terms of the *quantity of light* sent in a given direction in a nearly parallel beam, and not by its candle-power, which is a very different thing. The two concluding sentences of Mr. STEINMETZ's letter need the following qualification. The rays from the arc would proceed practically as from a point, diverging from it; the illumination produced by it would be inversely as the square of the distance from this point. But there is little or no such divergence with the search light, and therefore the candle-powers cannot be compared.

THERE are, as far as we know, only three classes of individuals who are more or less bound to hold an impartial position towards the question of continuous *versus* alternating currents. These are presidents of scientific societies, *ex officio*, consulting engineers, *ex professo*, and editors of technical journals, *coram publico*. But this attitude is made difficult by the weak arguments which are put forward by advocates of alternate currents and transformers. Disregarding their own strong points and the really weak ones of the continuous-current system, they bring forward all sorts of side questions and new inventions when they undertake to discuss relative advantages and economies. It is very rarely that we find an alternate-current man who can point to a satisfactory plant and district and a good balance-sheet and say, "This is all as it ought to be, and may be compared with a similar district supplied with continuous currents."

NOTWITHSTANDING high coal bills, blinking lights, and inability to run motors, alternating currents present most important advantages for certain cases, such as the lighting of the residential suburbs of a town, or for the rapid covering of a wide area in order to pick out the best customers. For the purpose of giving a fair hearing rather than for any convincing arguments that it contains, we print this week a long letter from Mr. R. N. LUCAS. He refers to an automatic switch. We have described two of these. Mr. TOMLINSON's, designed for sub-stations, was promised to save 26½ per cent. of the coal; we do not know that it has been used in practice. The other was an instrument of most formidable complexity. A diagram was submitted to us, and we gave a brief account of it some time ago, promising to look into it more closely after some practical expenditure of its working had been gained. Consumers are most unjustly charged for rental of transformers, but we do not know who was to pay for this apparatus. We regard the use of such a machine as a serious confession of weakness, a weakness in which we do not believe. After going into various figures, our correspondent assumes a 2½ per cent. fall on a low-pressure network and an 80·5 per cent. efficiency. We hope that sub-stations will be able to do better than this, even though Mr. LUCAS suggests that they have to make up 10 per cent. before they even equal it.

ACCORDING to the *Evening News'* interviewer, HARNESS is "not going to do anything until the articles are completed." We shall then see what we shall see. If someone would interview the Public Prosecutor we might get to know what he is waiting for. Perhaps for HARNESS to run away. It is satisfactory, from this point of view, that he is still with us; and that the Public Prosecutor has a chance of doing his duty. Meantime the *Pall Mall* continues its revelations, supplying materials for a score of indictments, if Sir A. K. STEPHENSON is thinking of doing anything. For the financial aspect of this business we commend our readers to last week's *Statist*.

Cable Interruptions and Repairs.—There are again no interruptions or repairs to record.

Kingston-upon-Thames.—The opening of the supply station, which was announced for last Saturday, has been postponed until November 4th.

Personal.—Mr. H. C. Marillier has resigned the editorship of *Lightning*. We understand that he is already well into harness in general journalistic work.

Municipal Electric Lighting.—A special meeting of the Kensington Vestry was held at 9 o'clock on Wednesday night last to consider the following resolution: "That the Vestry apply to the Board of Trade for a Provisional Order authorising the Vestry to supply electricity within the district over which it exercises jurisdiction."

Lamp-holders.—Our attention has been called by Mr. C. Scott Snell to his letter in our issue of April 18, 1885, in which he pointed out that he designed the arrangement of cross-wire loops for lamp-holders in 1882, whilst with Messrs. Woodhouse and Rawson, by whom he believes it was patented and who have made it from that day to this.

Electric Launches for Venice.—There seems to be some prospect of the appearance of electric launches on the canals of Venice. The Electric Launch and Navigation Company, which supplied the electric launches at the Chicago Exhibition, has, it is reported, disposed of a number of its launches to a company, which will put them in service on the Venice canals after the close of the Exhibition.

Clockwork Bells.—The mania for inventing strange things to go by springs, and "to be periodically wound up," has now spread to door bells, in the shape of a plausible imitation of the electric bell. You press a button, and a gong rings just inside the door as long as the button is pressed. For people who prefer that their visitors should hear the bell rather than their servants, this ought to be very useful.

Electric Lighting at Blackpool.—The plant at the new station comprises a 200 H.P. engine driving a 100-kilowatt alternator, two 100 H.P. engines driving two 50-kilowatt alternators, and three 60 H.P. engines driving three arc-lighting dynamos, and is capable of supplying current to 6,250 16 c.p. incandescent and 165 arc lamps. The contractors were Messrs. Hammond and Co., who have supplied their usual class of plant

The Geneva Water-Power Plant.—From the report of the Geneva Water-Power Supply Company it appears that over six millions of cubic metres of water have been distributed during the last year, under pressure obtained by pumping the Rhone water to a height, at a cost of 0·26d. per cubic metre. The water was supplied at a price of 0·35d. per cubic metre. Among the industries supplied in this manner is the electric generating station, which takes about 1,000 H.P.

The Electric Staff System.—Yesterday the working of the electric staff system was commenced on the Severn Valley Line of the Great Western Railway at Bridgnorth. For some time the line has been worked by the ordinary staff system, but the new working by what is known as the electric staff is by order of the Board of Trade. The electric system was tried in connection with a special train, which travelled several times between Hartlebury Junction and Buildwas Junction, and the result gave general satisfaction.

Digitized by Google

Testing Institution.—The first electrical testing establishment in Scandinavia has been opened at Stockholm, by Herr Azel Estelle, a well-known Swedish electrical engineer. The establishment is modelled on the Physikalischtechnische Reichsanstalt, in Berlin, and undertakes the testing of electrical apparatus by instruments supplied by the institution named, the drafting of plans for electrical installations and estimates, &c.

Royal Victoria Hall.—The following are the arrangements for science lectures at the above hall during November:—November 7th, Mr. Francis Bond, F.G.S., on "Norway and the Norwegians," with lantern illustrations; November 14th, Prof. H. G. Seeley, F.R.S., on "Skulls," with lantern illustrations; November 21st, Mr. James Swinburne, on "The Mechanics of Street Toys," with experiments and lantern illustrations; November 28th, Mr. Douglas Carnegie, on "The Philosopher's Stone, or the Royal Road to Health and Wealth."

Cornell University.—This American University, which is well known to our readers from the fact that it has developed an important section in technical education, has just been celebrating what one of our American contemporaries calls its "quadri-centennial anniversary," which is to say that it has been established over a quarter of a century. During that time, and under the direction of such men as Profs. Anthony, Ryan, and Nichols, this university has done a considerable amount of useful work in technical education and research.

British Awards at Chicago.—The following awards to British exhibitors at the Chicago Exhibition are announced:—British Government Postal Telegraph Department—(1) modern telegraph apparatus in operation, and (2) historical telegraph apparatus; Corporation of Birmingham, original Woolwich dynamo; General Electric Company (Limited), London, H. I. switches and other incandescent lamp fittings; and Mr. James White, Glasgow, electro-magnetic balances; London and North-Western Railway Company, London, application of electricity to boiler-shop tools, and electric train-staff and ticket apparatus.

Remarkable Decision in Telegraph Law.—The Supreme Court of Georgia held, in the recent case of Willingham *v.* Western Union Telegraph Company, that where a telegraphic message, delivered on Sunday for transmission, did not show on its face that it related to a subject matter which would render transmission and delivery a work of necessity or charity, and where there was no averment in the declaration either that the dispatch in question did relate to such a subject matter, or that the Telegraph Company, its agent or servant, was informed that it had relation to any such matter, the failure to transmit and deliver it on Sunday was not actionable.

Exhibition Lighting.—The incandescent light plant at the Chicago Exhibition is stated to be capable of keeping 180,000 lamps of 16 c.p. alight at once, if required, "which would be equivalent," says the *Engineering Magazine*, "to the consumption of more than 1,000,000 cubic feet of gas per hour." This calculation, says the *Journal of Gas Lighting*, is correct enough, so far as it goes. What is required to be added to it, however, is the observation that no gas engineer yet born would make an equivalent plant, unless he was reasonably assured of getting more profit out of the job than the Chicago Exhibition authorities are likely to realise from any part of their enterprise, electric lighting included.

Another First Inventor.—It seems, says the *Gas World* that the inventor of the lightning conductor was not Benjamin Franklin, but an Austrian, or rather a Bohemian monk, of the name of Prokop Dyivicz. He put up a lightning conductor, and very soon afterwards the building was struck. The building was saved; but the lightning conductor was apparently thought to be something uncanny, for he was ordered to take it down at once. After this he fell back into obscurity, though before that his researches had attracted a great deal of attention; and he died in 1765. The American papers have been discussing this matter; and regret has been expressed in America that there was no bust of Divis, as he is called there, to put up at the Chicago Exhibition.

Tri-phase Motor in America.—The first system of public supply in the United States for the practical, commercial use of the three-phase current for general distribution of power, light, and heat has been made at Concord (N.H.), where a plant of this character has been erected. The first motor was started on September 29th in an engineer's machine shop. This plant has been erected for the Concord Land and Water Power Company, which is developing the water power at Sewall's Falls, in the Merrimac. The three-phase generator and motor now in operation were made by the General Electric Company at its works at Lynn, and were erected by E. F. Carpenter, superintendent of the water-power company. The Company hopes to put in several hundred small motors to be operated from this station. It is intended to use the three-phase system for almost the entire transmission of light, heat, and power.

Fast Telegraphing in Boston.—A remarkable record in telegraphic annals, both for speed and accuracy, was made, says the *Electrical Engineer* of New York, at the main office of the Postal Telegraph Company in Boston recently. Assistant-manager Bagley sent 58 messages in the unprecedented time of 30 minutes. The messages were those of ordinary character, such as occur in the regular daily transmission of business, and averaged 10 words in the body, exclusive of the address and signature. This would be faster average time than that made by Gibson, the champion fast sender at the tournament held in New York last autumn, when that operator sent 97 messages in an hour. In the latest trial the address was abbreviated, but the body of the message was spelled out in full. It will be seen that at this rate of speed Mr. Bagley was sending at a rate that would dispose of 116 messages in an hour.

The International Tramways Institution.—At the meeting of this Society, held at Budapest on September 7th, 8th, and 9th, much interest was aroused by a long discussion on the question of electric tramways, which arose on a Paper read by Herr Schmidt on the subject, and which resulted in the almost unanimous adoption of a resolution to the effect that in view of the successful introduction of electrically-driven tramways, on both overhead and underground systems, on the Continent, on which greater speed is attained and greater traffic is obtained than on horse lines, the Institution recommends, in the public interest, electric traction to both public authorities and tramway companies, and advises the former to encourage companies having concessions to adopt electric traction by means of suitable grants of facilities. The members spent two days in examination of the very successful Budapest electric tramways system.

The New Caledonia Cable.—Sir Thomas M'Ilwraith, the retiring Premier of Queensland replying to the regret expressed by the Marquis of Ripon, the Secretary of State for the Colonies, at the action of Queensland and New South Wales in committing themselves to the laying of a cable to New Caledonia, which, its promoters claim, will serve as the first section of a trans-Pacific cable connecting Australia and Canada, remarks that the complacent policy of Great Britain has allowed foreign Powers to acquire territory in the Pacific to the injury of the future Australia, and he especially instances the establishment of a French convict settlement in New Caledonia. Sir Thomas goes on to contend that the construction of the cable between Queensland and New Caledonia will mitigate evils which already exist, and declares that if the protest of Australian statesmen had been promptly heeded in the past much inconvenience and injury would have been prevented. Queensland, he said, always favoured the construction of a purely British cable across the Pacific, and would warmly welcome the support of the mother country to such a scheme.

Long-Distance Telephones in America.—The last connection was made, says the *Western Electrician*, of Chicago, on the long-distance telephone line between Spokane, Portland, and Willamette points and Tacoma, Seattle and Puget Sound points, on October 2nd, thus completing the second longest telephone line in the world, involving an outlay of nearly $250,000. The route of the line is from Spokane to Garfield, thence down the Palouse River to Colfax, and from there across the country, *viâ* Almota, Pomeroy, Dayton, and Walla Walla, to the Columbia River at Wallula, then down the Columbia River along the line of the Union Pacific Railway to Portland, from which point one branch leads south into the Willamette Valley, and the other north *viâ* Vancouver to Olympia, Seattle,

Digitized by Google

Tacoma, and Puget Sound points. The main line is over 750 miles in length. The line between New York and Chicago, the longest in the world, covers 950 miles. Between Spokane and Portland there are but three stations permanently on the main line, viz., Colfax, Walla Walla, and The Dalles; but switches can be made at any of these points, and connection given to any of the surrounding towns.

Switzerland.—Some interesting developments of electric transmission of power and electric traction are now taking place in Switzerland, where the abundance of water-power enables electricity to compete with success with every other mode of power transmission. The Compagnie de l'Industrie Electrique, of Geneva, is now actively engaged in building eight electric cars, each fitted with 20-H.P. single-reduction motors, for the new line from Champel to Petit Sacconnex, which will pass through the centre of Geneva and will be about 5½ kilometres in length. This line is to be worked on the trolly system, the construction of which is being undertaken by the before-named Company. At Dijon it is expected to have four or five different lines of electric tramways running by next summer, and the equipment of 20 cars, of the same pattern as for the Champel-Sacconnex line, is being carried out by the Geneva electric company. As regards the utilisation of water-power, a scheme is under consideration for transmitting 3,000 H.P., taken from the Isère, half to Valence sur Rhone and half to Romans. The available fall is very low, and vertical turbines making 25 revolutions per minute are to be erected.

Electric Power Plant at Boxholm.—The electric power plant at Boxholm is approaching its completion. The works erected in 1886 having proved inadequate, says *Engineering*, and there often being a want of water, it was decided to go in for a new electric power transmission plant, coupled with a light station, and for that purpose to utilise the lowest of the waterfalls, which had not been used for several years. The fall is not perpendicular, but has an extension of about 500ft. In order to use the full height of the fall, it became necessary to build a canal along the stream, proceeding from the foot of the fall to the dam in front of the buildings, and the depth of which corresponds with the depth of water at the bottom of the fall. In this manner a fall of 20ft. was obtained, whilst it would otherwise not have been more than about half. In order to keep the water of the river apart from that in the canal, a wall about 420ft. long had to be built. The water is conveyed to five turbines, each of 50 H.P. The turbines and transmissions are on the ground-floor, whilst the dynamos, &c., are placed on the first-floor. Two dynamos, each of 225 amperes and 110 volts, supply the light, and another dynamo of 60 amperes and 220 volts supplies the requisite current to the electric railway. There will be in addition to these two good-sized alternate-current dynamos, besides a smaller similar dynamo for transmission of power to the works.

A New Method of Motor Suspension.—Among the improvements which the introduction by the General Electric Company of the United States of the new "G. E. 800" street car motor has brought into tramway practice is a new method of suspending the motor on the axle and the truck, whereby it is made to rest upon a resilient system, the weight being supported at a point immediately below the centre of gravity of the motor itself. This system of suspension is known as the cradle suspension. Immediately below the armature bearings are trunnions on each side of the motor, set in side bars which are pivoted at the front to a special casting, and supported at the rear end from link bars bolted to the truck frame. The front special casting is mounted upon six springs, two of which offer resistance to pressure upwards, and four resistance to the downward pressure. It will thus be seen that this modification is of significance in electric railway practice. The motor being set upon a spring-like cushion, the greater part of the dead weight is taken off the axle itself and is more evenly distributed to the axle bearings, and that part of the truck which can better stand the strain. This, in conjunction with the lightness of the motor, means economy of track maintenance and a decrease in the possibility of accident to the axles.

The Action of Electricity on Microbes.—The methods employed by M. D'Arsonval to determine the action of electricity on living matter have already been noticed in these columns. The process consists essentially in passing a current through a solenoid, in the interior of which the substance to be experimented on is placed. MM. D'Arsonval and Charrin, according to the *Lancet*, recently made some investigations as to the effects produced on microbes by the current, selecting for this purpose the bacillus pyocyaneus. A culture of this organism was placed in the solenoid. At the commencement of the experiment a tube of nutrient agar-agar was inoculated with two drops of the culture. After the lapse of ten, twenty, and sixty minutes respectively, further cultures were made on different tubes, which were all placed in an incubator for some hours. An examination of the tubes then showed that a luxuriant culture of the bacillus had grown in each; the forms of the colonies had undergone no change and were similar to those grown in central tubes; the pathological characteristics appeared also to be the same. The colour of the cultures, however, had been to some extent affected; for whilst in the first two tubes the organisms exhibited an intensely green colour, which was scarcely less vivid in the second than in the first tube, the colour in the third and fourth tubes was much less marked. These experiments seemed to show, then, that the electric current had some effect upon the organisms, although the action was not very marked. Further investigations in the same direction would be valuable and might possibly throw some light on the electrical state of the atmosphere as affecting the course of certain epidemics.

Madras Electric Tramways.—The Madras Tramways Company have taken possession of the freehold belonging to the Wesleyan Mission, Rundall's-road, Egmore, and commenced work, a number of workmen having been set to clear the site, dig foundations, &c. The successful tenderers for the erection of the car-sheds, offices, workshops, engine and boiler-rooms and power station are Messrs. T. Jones and Dumphy. The works will now, the *Madras Times* understands, be carried on with dispatch, and the prospects of the city having at last an electric tramway now seem near realisation. The car-sheds are being constructed to hold at present 30 cars, and admit of extension to accommodate 20 more. The connections with them will be made with the main line on the Poonamallee Road, and the lines in the sheds will be intersected with examination pits to allow workmen to get at the motors attached to the axles of the cars. The roof over these sheds, as well as that over the engine and boiler-rooms, will be pent with iron and wooden trusses and covered with Mangalore tiles. The workshop will be on the latest and most improved pattern, and well equipped, and the shafting will be driven by an electric motor supplied from the main dynamos. The engine-room will hold quadruple sets of Tangye's compound coupled non-condensing engine of 180 nominal horse-power each. These will drive a quadruple battery of Elwell-Parker dynamos, the output of each of which will be 500 volts 240 amperes—120 kilowatts; also two smaller dynamos, by the same makers, to develop 135 volts. The switchboard will have two double-pole cut-out switches, main switch and two shunt resistance switches with the necessary resistance coils, two ammeters of 300 amperes carrying capacity, two old meters and four-way switches, also circuit switches for lightning and conductor circuits. The boiler-room will be equipped with a battery of six Babcock and Wilcox boilers, each for 4,500lb. of evaporation, F. W. Berryman's heater, donkey-pumps, filters, and overhead watertanks. The whole of the premises will be lighted throughout with electricity, and a special feature will be that the men working in the shed at night will have hand-lanterns which can be attached to the main conductor and bring light to bear on the immediate spot required. The stores will be a rectangular building on the east side of the property, and in connection with the workshop. They will be terraced, and an upper story, to be utilised as storekeeper's office, will rise from over the courtyard in the centre. The whole structure, when completed, will form one of the interesting features of Madras. The first instalment of machinery has arrived by s.s. "Muttra," and Mr. Chalk, the Managing Director of the Company, is expected.

LAMP-HOLDERS.

(Concluded from page 674.)

The General Electric Company make two distinct kinds of holder. One called **Z** pattern has a bridge of china between the two terminals; this is prolonged round the terminals in the shape of a **Z**, thus carrying out the condition of the General Electric Company's "H.I." system of interposing a china bridge between metallic pieces carrying the current. It avoids any danger of short-circuiting inside the terminal due to stray

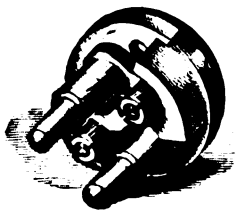

FIG. 16.—General Electric Company's **Z** pattern Base.

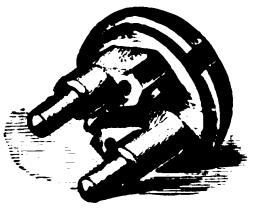

FIG. 17.—General Electric Company's A pattern Base.

strands of the flexible conductor. This terminal is shown in Fig. 16. The terminals of this lamp-holder consist of short screwed pins provided with one or more washers, and a long nut nicked at the end like a screw, and adapted for use with an ordinary bradawl screwdriver.

Their other kind, called the A pattern (shown in Fig. 17), allows the wires to pass straight through from the back, and holds them in that position by a side screw fixed in a block

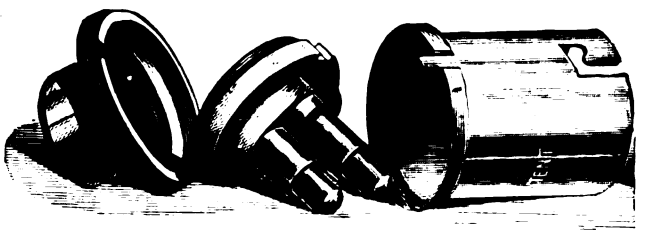

FIG. 18.—General Electric Company's Lamp-holder.

of metal, as in the "Ediswan" No. 14. The **Z** pattern is supposed to present the advantage that the wires must be bent in order that they may be twisted round the screw pins, and thus afford a considerable resistance, sufficient to take the weight of a pendant or shade. In the A pattern the wires need not be bent, and it is clear that the side screw cannot be always relied upon to withstand any longitudinal pull. It is unwise to rely upon the terminals in any case to take this

FIG. 19.—General Electric Company's Holder No. 3002, with Shade Carrier.

pull; a good cord grip should always be used for pendants or holders that are wired with flexible cord. With the A pattern it seems impossible for any loose strands to cause a short circuit with anything like careful work, for the wires need not project beyond the metal block. The A pattern of the General Electric Company presents some advantage over the "Ediswan" No. 14 in the position of the set screws, which are so arranged that rather more clearance is given between the heads of the screws and the outer barrel. Lamp-holders of this kind are often provided with a shade-carrying ring, as shown in Fig. 19.

The **Z** pattern presents an advantage over the A pattern and over the "Ediswan" No. 14 holder, when, owing to the arrangement of the fitting, a screwdriver cannot be used at right angles to the axis. However confined the situation, a small screwdriver can always be used to wire the holder.

Messrs. Burbey, Williamson and Joseph make, under licence, a lamp-holder almost identical with the "Ediswan" No. 14, the only difference being in the internal construction of the spring contacts, and in the use of "petramite," a highly insulating kind of porcelain, which is not liable to shrink in firing, and which can, therefore, be moulded with great accuracy.

FIG. 20.—Statter and Co.'s Lamp-holder.

Messrs. Statter and Co. make a lamp-holder (Fig. 20) closely resembling the standard pattern, but provided with a steel "grub" screw to fasten the holder firmly to the nipple, to prevent unscrewing of the holder when the shade-carrier is slacked back. When the holder is thus accidentally twisted, the wires may be pressed together, and if they have been skinned back too far a short circuit may take place.

Messrs. Poole and White make a lamp-holder, the base of which is glazed porcelain, and has a bridge separating the terminals as shown in Fig. 21. Messrs. Poole and White claim to be the originators of the system of dividing the metallic parts of a fitting by means of an insulating bridge.

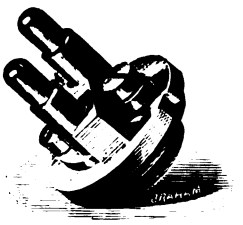

FIG. 21.—Poole and White's Lamp-holder Base.

FIG. 22.—General Electric Company's Lamp-holder, with shade-carrier and back-plate, No. 3018.

Messrs. J. H. Holmes and Co., of Newcastle, manufacture lamp-holders under licence, but confine themselves to the "Ediswan" pattern.

The Walsall Electrical Company make a holder (Fig. 23) which differs considerably from the modification of the "Ediswan" pattern in the mode of securing the wires. The buffer barrels are provided with saw cuts or slots near the bottom, and are attached to the china base by screws from the back of the base. In wiring, these screws are slacked, the wires are passed through holes in the base, and are inserted in the slots. On tightening the screws the barrels are drawn up to the base, clamping the wires firmly, and offering no liability to short-circuit from loose ends.

Messrs. Evered and Co. make a lamp-holder which was fully described in *The Electrician*, Vol. XXIX., p. 623.

We do not propose to describe switch-holders, because the demand is so small that the design has not yet received much attention, and most switch-holders leave something to be desired. There is no separate master patent for switch-holders, since Edison's 578, of 1880, in the fourteenth claim, speaks of "a circuit-controling device for controling the circuit to one of the contact plates." The switches hitherto proposed are of three kinds, one with a handle to be turned about a quarter turn, as in most switches; a push switch with a button on either side of the holder; and a modification of the tumbler switch. The ordinary turn switch, unless provided with a weak spring and feeble contact, cannot be worked with one hand; but the two other patterns allow this. The switch must be arranged above the shade, as a rule. The chief use of switch-holders is in public buildings and offices, where many pendants are used, and where the lights have to be separately controlled. In the large sorting halls of the General Post Office, for example, separate switches for each lamp would have entailed a very large expenditure on extra wiring. But few, if any, switch-holders of the two latter kinds have been made of porcelain; the working parts are generally mounted on vulcanised fibre or ebonite.

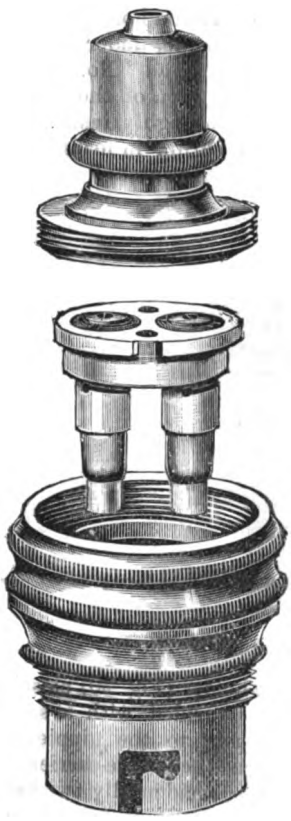

Fig. 23.
The Walsall Electrical Company's No. 93 Lamp-holder.

Lamp-holders are supported in three ways, by screwing to the nipple of a bracket or fitting, by a back-plate, or by suspension from a pair of wires. There is nothing to be said about the first method, except to commend Messrs. Statter's device for preventing the unscrewing of the holder, and the use of ⅛in. thread, instead of ⅜in. for most cases, thus allowing the ordinary insulated wires to be led right up to the terminals of the holder. A holder with a back-plate for screwing direct to a ceiling block, is shown in Fig. 22. For the lighting of cellars and larders, where there is but little room to spare, these fittings are useful, as well as in bath-rooms, where the whisk of a towel may carry away a lamp fixed to a bracket or pendant.

Fig. 24.—Belsize Holder, with Bridge.

Fig. 25.—General Electric Company's Lamp-holder, with cord-grip, No. 3,003.

Cord grips should always be used for pendants. Knotting the wires in ceiling roses is a clumsy expedient, and is occasionally done in lamp-holders. The bridge system, as shown in Fig. 24, has been employed. It will withstand a good pull, but it takes up some room, and has only been used in rather large holders, with screwed china caps. The common cord grip, which we believe is not patented, is shown in Fig. 25, and consists of a split wooden, or ebonite, plug, with a coned end and holes for the wires. The plug is held by a coned brass cap, which compresses the halves of the plug on the wires. A similar arrangement is used for ceiling roses and wall plugs, in which soft rubber can be used with advantage instead of wood.

The modern lamp-holders which we have described all fall under the Dornfeld patent. As this does not expire until January 28, 1898, there seems to be room for the manufacture of a simple lamp-holder clear of this patent. This, of course, could not be done until the Edison master-patent expires in February of next year. Considering the stress that Dornfeld put on the use of springs, it would seem that rigid pins and a spring bayonet would not be a mechanical equivalent. Nor is any spring really wanted; the lamp caps are always flat, and could be held tight against solid contacts by a screw clamp. The alternate heating and cooling of the holder would have to be provided for.

We have in conclusion to express our thanks to the Edison and Swan United Company and to their various licencees for the loan of the blocks used to illustrate these articles, and in particular, to Mr. G. Binswanger, of the General Electric Company, for information about the patents.

Erratum.—On p. 638, in the first of these articles, for A. Swan's patent No. 5,153, read 5,158.

PRIMARY BATTERIES IN THEORY AND PRACTICE.*

BY W. R. COOPER, M.A.

PART II.

(Continued from page 677.)

The number of primary batteries is so great, and the possible variations so numerous, that only a few of the chief points of interest can be touched upon in a Paper of this description. Before, however, proceeding to the various commercial forms, it may be well to consider the effect of changing the depolariser in a double fluid cell.

Mr. Sprague has conducted some experiments, in which the same quantity of each depolariser was successively employed in a porous pot, containing the carbon plate. The zinc and sulphuric acid were placed in the outer vessel. The cell was connected up through a galvanometer and a copper voltameter, the resistance remaining constant, and was allowed to run until the current fell to a certain small value. In this manner, equal quantities of nitric acid, sodium bichromate, potassium bichromate, and chromic acid were tested; the results being graphically shown in the curves that are reproduced in Fig. 11. It will be noticed that a much greater quantity of electricity was obtained by using HNO_3 than by any of the other substances. The very great difference between sodium bichromate and potassium bichromate is much greater than might have been expected, and indicates that the sodium salt is very much to be preferred in bichromate cells to the salt of potassium, which is more generally used. The actual ampere hours are given as follows:—

Nitric acid	16·0	ampere	hours
Chromic acid	6·4	„	„
Sodium bichromate.....	5·0	„	„
Potassium bichromate...	1·7	„	„

* Paper read at a Students' Meeting of the Institution of Electrical Engineers, May 19th.

Digitized by Google

Since the internal resistance may have been considerably different in the four cases, these results do not appear to be altogether comparable.

A classification of cells may be made in a variety of ways. Perhaps the simplest is that of wet and dry cells; but some of the dry cells are very decidedly wet, so that the distinction is a somewhat superficial one. Cells may also be classed according to the number of electrolytes employed; or, again, according to the nature of the electrolyte which may be acid, neutral, or alkaline. This last method is perhaps to be preferred, though only applicable to wet cells.

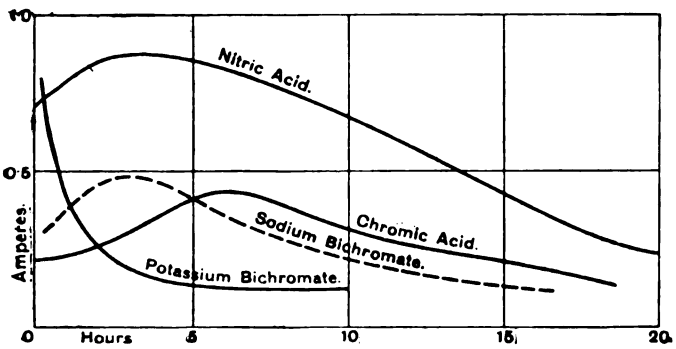

FIG. 11.—Curves showing Relative Work of Depolarisers.

Acid Cells.

All batteries employing an acid electrolyte possess certain disadvantages. There is always a tendency to local action, which increases as the cell is used, until the zinc is reamalgamated. A porous pot is generally necessary owing to the use of a fluid depolariser, and this increases the internal resistance, thereby diminishing the efficiency. Also for ordinary use, an acid is objectionable as it corrodes the contacts and fittings, and is destructive generally.

Neutral Cells.

Of those cells employing a neutral electrolyte, the most prominent are the various modifications of the Leclanché cell introduced in 1868. This cell is so well known that a description of it is almost superfluous. It consists essentially of a rod of carbon packed into a porous pot with gas carbon and peroxide of manganese, which forms the depolariser. The whole is placed in an outer vessel with ammonium chloride and the zinc rod. Such a cell is simple, but it has a variety of disadvantages. It polarises rapidly, but partially recovers by rest. The porous pot necessarily increases the internal resistance. Also the electrolyte evaporates if the cell is used for long, or is placed in a warm position; and the zinc rod is eaten away at the surface of the liquid, instead of in a uniform manner, so that the lower part of it drops off before the whole of the zinc is consumed.

A variety of forms has been devised to overcome these defects. M. Leclanché has introduced an agglomerate of carbon and manganese peroxide, in place of the ordinary mixture that is employed. In order that the depolarising action should not be limited to the surface, it is necessary that the agglomerate should be very porous. This is effected in a simple manner by adding a small quantity of sulphur to the carbon and manganese. The mixture is then pressed into the required forms, and baked, when the sulphur volatilises off, leaving an agglomerate that is exceedingly porous. This can be bound on either side of a carbon plate, thus doing away with the necessity of a porous pot, and reducing the internal resistance to as low a value as 0·25 ohm.

But the most recent form of Leclanché cell is that known as the Leclanché-Barbier cylindrical agglomerate, the composition of which differs somewhat from that of the agglomerate blocks just described. These cylinders are composed chiefly of peroxide of manganese and plumbago, which, being a good conductor, takes the place of the carbon collecting plate, this being entirely dispensed with. The zinc rod is placed in the centre of the cylinder, and is supported by a disc of paraffined wood, thus reversing the usual arrangement of the elements. The cylinder itself does not touch the bottom of the containing vessel, but is supported by a ring of metal, which is cast round the top, and rests upon a rubber seating, at the same time serving as the positive terminal. In this way practically no evaporation can take place, although any gas that is formed may escape. The cell may be left for long periods without attention; it is readily taken apart, and creeping of the salt is entirely absent. The internal resistance is 0·4 ohm. When subjected to the Post Office test of being closed through 10 ohms resistance until the current falls to half the initial value, it shows a very good discharge curve, running continuously for 17 days before this state is reached, whereas the old porous pot form reaches the same condition in six days (*see* Fig. 12).

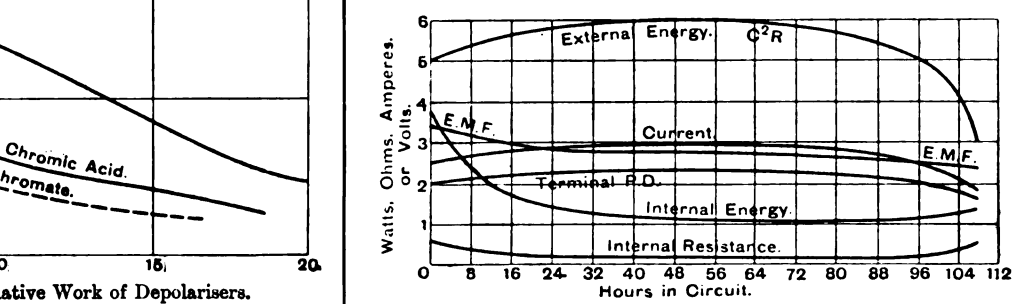

FIG. 13.—Curves of Edison-Lalande Battery. (Four Cells in Series.)

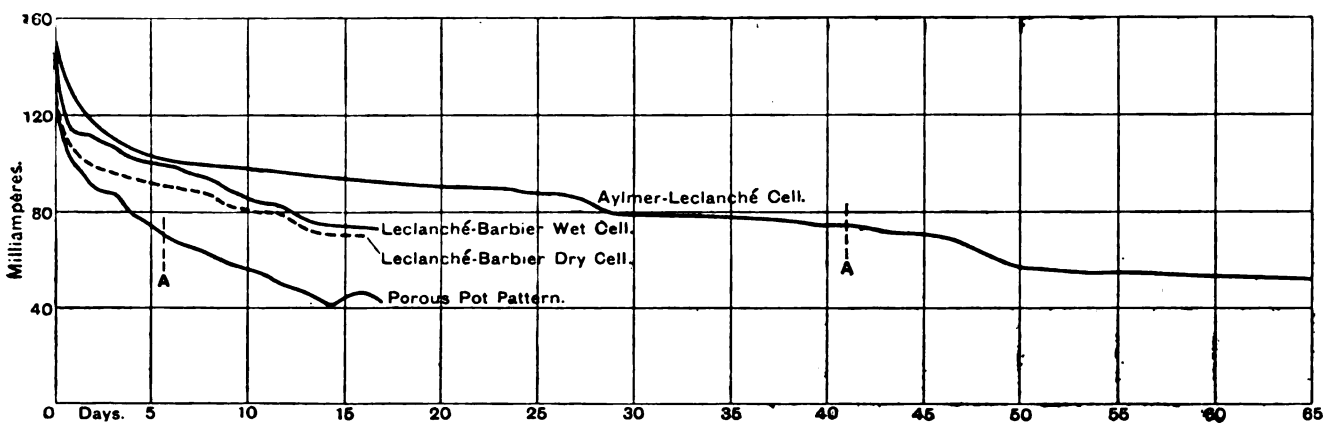

FIG. 12.—Comparative Curves of Discharge of Leclanché Cells, closed through 10 ohms Resistance. Half Initial Value of Current Reached at Points A.

Ammonium chloride, however, cannot be employed with the last kind of agglomerate described, as it destroys the porosity. To overcome this objection M. Leclanché has introduced a special exciting salt, the exact nature of which is maintained a secret. This salt has the very considerable advantage that it acts uniformly upon the zinc rod, so that the latter is almost completely consumed before replacement is necessary.

By surrounding agglomerate blocks with the zinc plate, as in the Aylmer-Leclanché cell, as low an internal resistance as 0·2 ohm is obtained. This arrangement appears to largely increase

Digitized by Google

the output, which amounts to 90 ampere-hours when the cell is placed in circuit with 10 ohms resistance, the current only falling to half its initial value after a continuous run of 41 days, as seen by the curve of discharge in Fig. 12.

The curves of discharge which are shown, though not strictly comparable, are interesting as illustrating the advances which can be made by modifications of one form of cell.

Before leaving the subject of Leclanché cells it may be well to add a few words as to the electrolyte. Considerable annoyance is caused by creeping of the salt if means are not taken in order to prevent it. Two methods are in general use. In this country the upper part of the pot, as also the ends of the Zn and carbon rods are coated with black ozokerite. The only objection to this is that it is liable to chip off from the zinc, and thus to afford no protection after a little time if subjected to rough usage. On this account it is found better to employ paraffin wax, the zinc being left sufficiently long in the melted wax to assume practically the same superficial temperature.

In place of ammonium chloride, common salt is sometimes used. This is cheaper; but it is found to be exhausted in a shorter time than the ammonium salt, which is to be preferred on this account.

A new exciting salt, known by the name of Electrogen, has been brought to my notice as being very suitable, and appears to give satisfaction on the Continent. Upon applying to the agents, Messrs. R. W. Greef and Co., they kindly forwarded me a sample and full particulars, except the composition of the salt, which is maintained a secret. It is claimed that, by its use, 85 per cent. of the zinc is rendered serviceable; whereas only 40 per cent. is available when ammonium chloride is employed, owing to incrustation on the zinc, which is difficult to remove, and results in only partial exposure and unequal wearing of the plate. This does not occur in the case of Electrogen, and the zinc is easily cleaned. Also the E.M.F. is higher, and the electrolytic resistance constant. It also appears that, although the cost of this salt is greater, the cost of maintenance is really less, a smaller quantity being required than in the case of ammonium chloride in the proportion of 60 per cent.

Alkaline Cells.

The cells of this class, like those of the previous one, are generally of the one-fluid type, making use of a solid depolariser, and employing a solution of caustic potash or soda.

One of the most successful cells of this kind is that known as the Edison-Lalande. The elements are zinc, caustic potash, and black copper oxide, which, at the same time, serves as a depolariser and as the negative plate. When the cell is in action, a double salt of zinc and potassium is formed, hydrogen is liberated, and the copper oxide is reduced. The copper plates are blocks of the compressed oxide, which has been ground to a fine powder. The zinc plates are placed on either side of the blocks of oxide, thus reducing the internal resistance as low as 0·025 of an ohm in the 300 ampere-hour cell. They are made up to as high a capacity as 900 ampere hours. Unfortunately the E.M.F. is low, being only 0·75 volt, and the expense is rather heavy. But it is a convenient form of cell, and the deterioration upon standing idle for twelve months is said to be only one-half per cent. The discharge curve of a 300 ampere-hour cell is very constant, as shown by the diagram (*see* Fig. 13).

Dry Cells.

What is generally known as the "dry pile" has been familiar from the very beginning of galvanic electricity. Volta constructed one of zinc and copper plates with wet cloth. Zamboni made use of discs of paper covered on one side with tin and on the other with black oxide of manganese. Such piles cannot give anything but the feeblest current, for very little chemical action can take place, and this is essential to the production of current. Hence no dry cell can be really dry if useful work is to be obtained from it: as soon as it becomes dry it also becomes useless.

On account of their great convenience, a large number of attempts have been made to produce a really serviceable dry cell. Minotto used sand and $CuSO_4$; Wolf, Keiser, and Schmidt tried sawdust and cellulose; Desruelles filled a Leclanché with asbestos fibre and spun glass; and Pollak made use of a gelatine glycerine. The first one that was really successful was the Gassner cell, which appeared in 1888. This cell consists of a zinc-containing vessel, which forms the positive element, and contains the negative element, which is a mass of carbon. The remaining space is filled up with a jelly, consisting of zinc oxide, ammonium chloride, sulphate of lime, chloride of zinc, and water. It was found to compare favourably with the Leclanché cell of that date, and caused some surprise by the discovery that it might be charged, like a secondary cell, when exhausted—a property which appears to belong generally to dry cells.

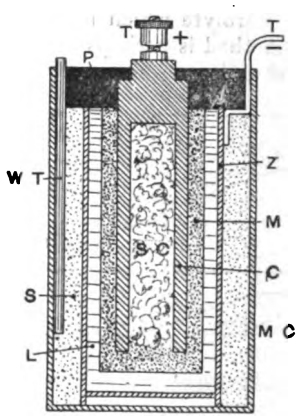

FIG. 14.—Hellesen Cell. Vertical Diagonal Cross-Section.

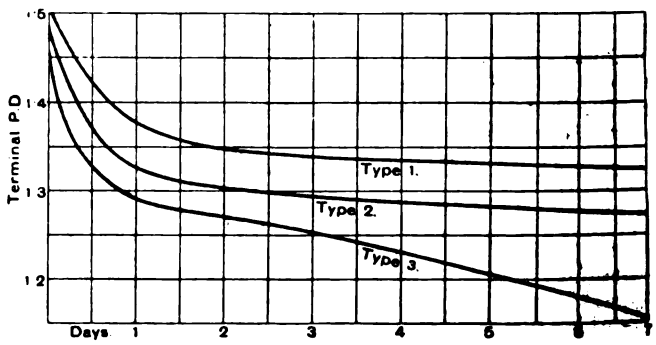

FIG. 15.—Discharge Curves of Hellesen Dry Cells, closed through 50 ohms.

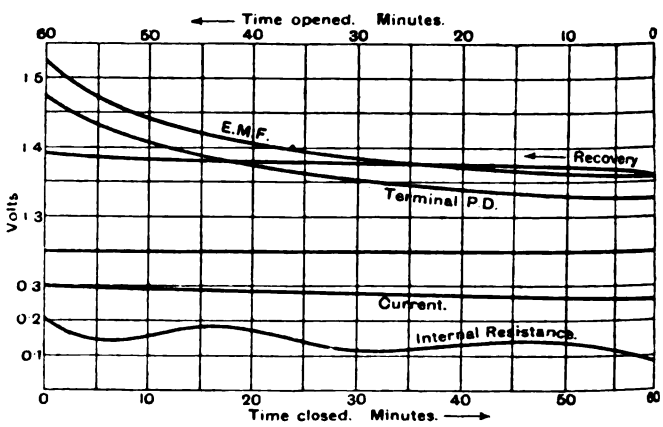

FIG. 16.—Curves of Hellesen Dry Cell, closed through 5 ohms, for 1 hour.

The Gassner cell, however, is not reliable. The polarisation is considerable and the curve of discharge is very acute. They are also liable to become short-circuited by leakage or dampness, and have therefore generally been superseded by other forms.

More recently the Hellesen and the E.C.C. cells have come largely into use. The Hellesen cell consists of a hollow carbon

Digitized by Google

filled with silicate cotton, and surrounded first with a black paste, then with a white paste, and finally by a Zn containing vessel. The whole is packed with sawdust into the outer case, and the top run in with pitch (*see* Fig. 14*). The black paste appears to consist chiefly of carbon and manganese peroxide, with the oxides of silicon, magnesium, calcium, and

Iron. The white paste consists of water, lime, ammonia, and the oxides of zinc and magnesium.

This cell is capable of some very good work, as shown by the curves of discharge (Figs. 15 and 16), which are reproduced from several that have been obtained by Messrs. Siemens, but its recovery from polarisation does not appear to be very rapid.

The E.M.F. is 1·5 volts, and the internal resistance varies from 0·2 ohm in the large size to 0·5 ohm in the smallest.

The construction of the E.C.C. cell is more simple. It consists of a carbon rod in a zinc containing vessel, the rod

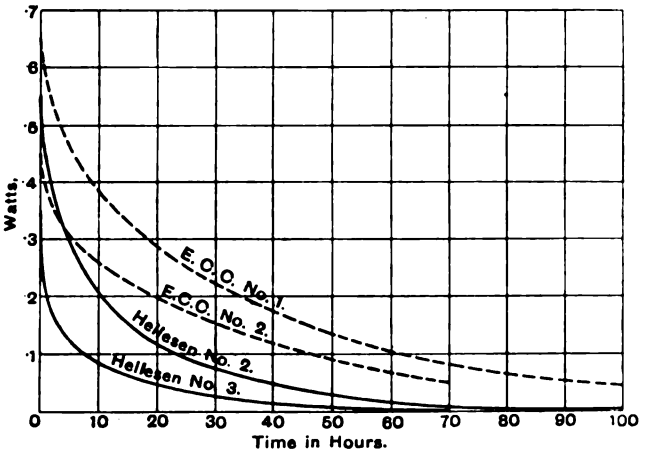

Fig. 20.—Output Curves of Hellesen and E.C.C. Dry Cells.

being surrounded first by a black, and then by a white paste. The top of the carbon is packed with silicate cotton and run in with pitch (*see* Fig. 17). The black paste consists chiefly of nearly 50 per cent. of carbon, with ammonia, water, the oxides of manganese, magnesium, calcium, and iron. The white paste consists chiefly of lime, ammonia, water, and chlorine.

Prof. Jamieson has recently carried out some comparative tests of these two cells, which appear to result somewhat in favour of the E.C.C. A few of the numerous curves of comparison are reproduced in Figs. 18, 19, and 20.

The "E. S." dry cell also appears to give satisfaction. The E.M.F. is 1·56 volts, and the internal resistance varies from 0·75 ohm to 0·20 ohm. Further particulars are not to hand.

The disadvantage of all these cells is that when once they are dry they are perfectly useless. This difficulty is overcome in the Leclanché dry cell, which is practically a Leclanché-Barbier cylindrical agglomerate, in which the exciting salt is held by some kind of cement. The top of this cell is simply closed by a disc of wood. If it becomes dry, it is only necessary to pour in some water which is absorbed, the surplus being removed, and then the cell is fit for work. It will be seen that the discharge curve falls but slightly below that of the wet cell (*see* Fig. 12). The E.M.F. is 1·5 volts, and the internal resistance in the two sizes manufactured is 0·5 and 0·6 ohm respectively.

A dry Leclanché cell is also made in which the exciting salt is held by gelatine ; this is prevented from drying by the addition of a few drops of carbolic acid.

(To be concluded.)

Electric Elevator Test.—A Frisbie electric elevator in the car-house of the Consolidated Street Railway, Worcester (Mass.), has recently been successfully tested. The trial test, says the *Electrical Engineer* of New York, consisted in raising one of the heavy cars to the upper floor. The elevator is said to be the largest electric elevator ever built in the United States. It consists of a platform 34ft. long, 15ft. high, and 10ft. wide, weighing 6¼ tons. This is guided at four points, and suspended in the centre by wire ropes, any one of which is capable of lifting a maximum weight of nine tons without danger of breaking. The steel beams which carry the sheave wheels, over which these ropes pass, weigh with their supporting columns more than four tons. The motive power for this elevator is supplied by a 20-H.P. electric motor of the Westinghouse make. This motor derives its power from the trolley circuit. The railway company will use it for lifting their cars from the ground-floor to the second story of their building whenever storage or repairs are desirable.

* Figs. 14, 17 . . . 20 are reproduced (by permission) from "Comparative Tests of Hellesen and E.C.C. Dry Battery Cells," by Prof. Jamieson, read before the Philosophical Society of Glasgow, 1893.

SPECIAL NOTICE.

With the issue of "THE ELECTRICIAN" of the 10th November, 1893, will be published (Gratis to Subscribers) a fine STEEL-PLATE PORTRAIT of

Mr. JOSEPH WILSON SWAN.

The present number of "THE ELECTRICIAN" completes Vol. XXX. With next week's Number will be issued (Gratis) the Index to the Volume.

READY NEXT WEEK.

Volume XXXI. of "THE ELECTRICIAN," price 12/6; post free, 13/; abroad carriage extra.

Cases for binding Volume XXXI., price 2/0, post free, 2/3.

The Publisher is able to supply a set of the Volumes of "THE ELECTRICIAN" complete except for three Nos. Price on application.

ORTHODOXY IN SCIENCE.

Hard pressed for a definition of orthodoxy, a once noted exponent of it explained that by orthodoxy he meant his own "doxy" and by heterodoxy another man's "doxy"; a definition more commendable for its wit than its accuracy. It is indeed true that the way in which we hold our opinions is almost of more importance than the opinions themselves, and a good-humoured light-hearted orthodoxy of the kind thus defined, if it be within human attainment, would obviously be devoid of the disagreeable features which have hitherto marked the crystallisation in an ordered system of previously fluid beliefs or theories; a process of crystallisation which we have no reason to suppose that modern science more than any other human movement will ultimately escape.

Already some of us are inclined to resent any questioning of the correctness of our scientific fundamentals as rank heresy, and to imply that refusal to admit the logical sequence of the superstructure which has been built upon these fundamentals, proceeds from mere midsummer madness. It is not, of course, particularly conducive to the peace and quiet of a scientific mind to be called upon at frequent intervals to stand and deliver good and sufficient reasons for the scientific faith within it, but the discomfort which arises from such disturbances of our philosophical complacency is as nothing compared with the bracing effect of these cross-examinations

Digitized by Google

by cross-grained critics and the wholesome restraint they exert upon fantastic speculation. The triumph of science one is at times tempted to think has been too complete. It has built up for itself, as it were, a walled city, seemingly impregnable; within there is indeed plenty and to spare of debating and discussing and winnowing of wheat from chaff, but from without there is no enemy to fear. The quiddling criticisms of minds from which all freshness and originality have been carefully trained away are no substitute as a restorative for the vigorous onslaughts of an acute outsider. The rough-and-ready way in which a knowledge of science was formerly for the most part acquired was no doubt destined to pass away and give place to something more systematic; but that there were compensating advantages, even the Germans themselves, to whom we defer so readily in these matters, were not slow to acknowledge. "Just because you were not passing through the usual training of the German scientist, the Academy specially counted upon you," said Du Bois-Reymond on the admission of Werner von Siemens into the Royal Academy of Science of Berlin twenty years ago; "not exactly in the sense that the unusual way in which you soared aloft is a true sign of unusual power, but because thereby, as we commend in many English physicists, your view remained fresher, your apprehension less confused, your judgment clearer, than if you, like others, had been brought up in the dogmas of the school." Yes, the passing of all minds through the same mould must inevitably lead to the turning out of minds of the same pattern, and the dead weight of orthodox authority which pressed heavily upon the mind even of a Faraday is likely to crush out all thought of independent inquiry from minds "brought up in the dogmas of the school," that is to say, taught to run in a groove, the right one it may be, but still a groove. "The respect which I entertained towards the names of Epinus, Cavendish, Poisson, and other most eminent men, all of whose theories, I believe, consider induction as an action at a distance, and in straight lines, long indisposed me to the view I have just stated"—namely, "that electrical action at a distance never occurred except through the influence of the intervening matter." So wrote Faraday in the introductory remarks to his investigations, at once ingenious and conclusive, on static induction. A properly minded man would, no doubt, have vastly preferred to have left such high matters exactly as he found them as by scientific orthodoxy established and to have earned the encomiums of his contemporaries by some elaborate action-at-a-distance straight-line mathematical investigation.

We do not suggest that there is any immediate likelihood of the establishment of a rigid "doxy" within the domain of science, but the past history of all human movements points to such a possibility, or rather probability, and signs are not altogether wanting that the tide may before long set strongly in that direction. The increased and increasing respect paid to science and scientists, the growing demand for scientific instruction, the ever widening application of science to every day problems, each by itself altogether admirable, tend in the aggregate to foster that pride of caste which in turn tends to somnolence and dependence on tradition and constituted authority rather than alertness and reliance on superiority of argument. The race of philosophers who pursue their inquiries "zealously yet cautiously, combining experiment with analogy, suspicious of their preconceived notions, paying more respect to a fact than a theory, not too hasty to generalise, and above all things, willing at every step to cross-examine their own opinions, both by reasoning and experiment," is not one that long survives after the spirit of antagonism that gave it birth has disappeared.

On the other hand, it may be very wasteful of valuable time to seek to stay the crystallising processes which result from an increasing confidence, on the part of scientists, in the premises or foundation of their constructive work. A person quite outside the region of science, one not trained in scientific thought—an enemy outside the city walls, as it were—would, in the present advanced state of science, be utterly incompetent to question the validity of its foundations. The looseness of his ideas and the jargon of his utterance would repel him from every scientific thinker. And men of science themselves are scarcely likely to institute any very rigorous direct investigation of the ultimate foundations of science. Firstly, because they would be thereby led into the intricacies of metaphysics without finality: secondly, because every fresh discovery in science, every new stone laid on the foundations, adds to their already strong conviction that those foundations are trustworthy and properly laid. The natural processes of elimination, and of survival of the fittest, which will in time weed out from science all those errors which have no legitimate basis in its foundations, must necessarily lead on towards a crystallisation of science, or the definition of an "orthodoxy." But we are comforted by the reflection that the stereotyping processes are natural, not arbitrary; they are the outcome of logical thought and not the dogmatic formulations of powerful bigots.

REVIEWS.

Minutes of Proceedings of the Institution of Civil Engineers, 1892-93. Part. IV. Edited by James Forrest, secretary. Published by the Institution.

This fourth and last volume of the *Proceedings of the Institution of Civil Engineers*, well filled as usual with communications of great interest, and numerous abstracts from foreign publications, contains one Paper which stands out from among the rest. Willans on "Steam-Engine Trials" is a sequel to the Paper on "Trials of a Non-condensing Steam Engine," read before the Institution of Civil Engineers in 1888. These two Papers together constitute the most complete series of experimental investigations that have been made on any kind of steam engine. In these Papers Mr. Willans did not in any way put forward the engine which he had designed as a peculiarly valuable one, but treated it, as Capt. Sankey observed in the discussion, merely as a piece of apparatus employed in making experiments of purely thermo-dynamical interest. Among the objects of these later trials were, to study the action of the steam in its passage through the several cylinders of compound and triple expansion engines; to observe the effects of speed, pressure, and temperature on initial condensation, and on economy generally; to fix the best ratio of expansion with any given steam pressure; to ascertain the ratio of the theoretical mean pressure to the pressure observed—called by the author the plant efficiency; to ascertain the ratio of the work done by each pound of steam to the work due from it—the thermal efficiency; to determine the pressures beyond which it is desirable to use a compound or triple-expansion engine; to determine the most economical method under various conditions of reducing the power of an engine; and to consider the advantages of jacketting. The Paper, of which the brief official abstract has been already printed in these columns, plunges at once into the "ideal efficiency" and the use of Mr. Macfarlane Gray's $\theta\phi$ diagram, which does not seem to have found its way yet into text books, and for a description of which a Paper read before the Institution of Mechanical Engineers in Paris in 1889 must be consulted. It is shown that owing to the cutting off of the toe of the indicator diagram, a much larger fraction must be

Digitized by Google

lost by incomplete expansion in a condensing than in a non-condensing engine. The difference between the practical and the ideal temperatures in the former case is 60deg. while in the latter it is only 14deg. Diagrams are given showing the limit to the number of expansions in a very clear manner. It is shown that with 150lb. pressure (absolute) the limit theoretically is 17 expansions, but very little is gained after 12 or 13; in the last third of the length of the cylinder only 3 per cent is gained. One of the most interesting parts of the Paper to a student of thermo-dynamics is the localisation of the losses on the θ ϕ diagram. This part is by no means easy to follow, and might perhaps have been divested of some of its difficulties had the author lived to prepare the Paper for presentation to the Institution. The last section deals with the important question of the economical value of automatic expansion gear as a means of reducing the power of an engine.

Automatic expansion gears are so often recommended for electric light work that this matter deserves the attention of electrical engineers. It has been ungenerously suggested by some, who neither knew Willans nor perhaps much about steam engines, that he disparaged these gears because they could not readily be applied to his engine. It is only necessary to shout loudly enough at some persons to effectually convince them, and it is perhaps thus that the reputation of the Corliss engine was made.

"The economical value of automatic expansion-gear is usually much exaggerated, and the merits of Corliss valve-gear and of other methods of varying the power by changing the ratio of expansion, have been extolled until it has almost become to be believed that the control of the cut-off by the governor has some occult effect on economy, even when the load does not vary." When a comparison was made between a throttled engine hardly expanding at all, and using low-pressure steam and an engine doing its ordinary load with a three-fold or four-fold expansion, automatic cut-off showed marked economy. "As pressures increased, and engines were compounded, the ratio of expansion necessitated by the use of two or three cylinders, approached more and more closely to that (sooner or later reached in all engines) beyond which there is no improvement in economy. hence the economical value of automatic expansion necessarily became less and less." The author found that "in the case of an engine working comparatively non-expansively at full load, like the simple engine, the gain by cutting off earlier in order to reduce the load is great. In the compound engine, on the other hand, the gain rapidly decreases as the ratio of expansion at full load increases; whilst in the triple engine the economical value of automatic expansion gear is almost inappreciable. The question apparently turns on the question of the load at which the normal work is done. On an electric railway using compound engines necessarily working under a fluctuating load, it is probably desirable to use automatic expansion gear, because, by that means, engines arranged to work at an economical ratio of expansion at their normal load, may be made to give off momentarily much greater power at a slightly increased cost. In central electric-lighting stations it should be the aim of the engineer to so arrange the size of his generating units that the engines at work may be at all times, as far as possible, fully loaded. Under these conditions, any slight gain, when the power is reduced due to the action of automatic expansion gear, is not of vital importance, seeing that it is the gain due to one only among a number of engines, especially as the gain seems almost to disappear when high-pressures and triple-expansion engines can be used together."

In opening the discussion, Mr. Mark H. Robinson said that up to a certain point the practical man might ignore the present Paper and others like it, but if he aspired to design economical steam engines he might derive more good from the study of, say, Mr. Macfarlane Gray's diagram than from many portfolios of working drawings.

The danger which, as many thought, now threatened English engineering lay in the more thorough education and the superior mathematical knowledge of so many foreign engineers. When there was a break-down to set right in a hurry, or a day's emergency work to be done in an hour, then might he find himself in the hands of an Englishman, but he dared not shut his eyes to the progress of scientific engineering abroad. Essentially a practical engineer, the author began his work with a distinct prejudice against theory, and against the mathematical treatment of the steam engine, but he ended by becoming one of the leading exponents of the scientific treatment of the subject, simply because, as a true engineer, he could not but recognise its necessity.

Mr. Robinson dwelt upon the loss occasioned by cutting off the toe of the diagram, and showed that there was no use in carrying the expansion below 6lb. (absolute) at release. He suggested that the law of total steam consumption, which is represented graphically by a straight line, should be called the "Willans law." In the course of the discussion Prof. Kennedy, adopting this expression, said that it was strange that it had been customary to plot curves per indicated horse-power hour, without taking the trouble to plot the actually observed quantity, the weight of water used per hour. Prof. Kennedy developed this law very considerably, and showed that with a refrigerating machine, which was an engine working backwards thermodynamically, the straight line law held good. He showed a large number of examples on several diagrams, one of which included tests of a Parsons turbomotor lying in a straight line within the general limits.

It might be interesting for members to know how far results in practice bore out the figures given in the trials of Willans engines. He had frequently, during eight, nine or ten consecutive hours of ordinary work in an electric lighting station, measured all the water, and noted all the power, and the points on the curve at which the work of each engine was done: and had then compared the water actually used with that which ought to have been used; and he had found that it came within about 5 per cent. a difference not more than might be expected from the feed-pumps and the general waste. For results over a whole week, where the nights came in and when also the starting and stopping was included, it was not within 5 per cent., but was more like 10 per cent., and often considerably more. There were losses between the boiler and the engine due to the leakage of valves, to open drains, to condensation in pipes, and to several other causes which he feared had not yet been explained. Taken altogether these losses were considerable, and gave a good deal of trouble.

Mr. Crompton directed attention to the accurate measurement of steam by a Willans engine as by a steam meter. This fact had been of enormous use to him in locating the losses that existed between the consumption of coal and the development of power. Over and over again it had been found that the monthly fuel account did not agree with what it should be when calculated from the estimated value of the boilers and engines as power-producers; but in every case, after due allowance had been made for ascertained losses, the Willans engine had been cleared from blame, and had given results varying not more than 2½ per cent. from the results claimed for it by the makers when they sent it out.

The interesting discussion on this important Paper was closed by Capt. Sankey, who dealt in great detail with the points raised by the speakers, and contributed a good deal of very useful information based upon results not included in the Paper.

Personal Recollections of Werner von Siemens. Translated by W. C. Coupland. (London: Asher and Co. 1893.)

In this autobiography of Werner von Siemens we find thrilling adventures on sea and land hardly to be surpassed in any book of fiction. Indeed, in the adventure with a water-spout and the occasion on which he and his horse both fell over a precipice and alighted unhurt, each on his feet, the author appears to have had a charmed life. The book is but indifferently translated, which perhaps brings into evidence the *naïveté* of style and the simplicity with which the success of his family and the value of his own work and suggestions is treated. But it is a book which must be read by almost any one with keen interest, not only from the intrinsic value of the work and observations of the writer, but because of the interest of his character. Despite some touches of melancholy in the whole life is to be noted that singular absence of regret which is so often found in the natures of great men; and this not so much from an uninterrupted flow of prosperity, but due rather to an inherent hopefulness, a sort of practical fatalism of character, and an intense enjoyment of work, and indeed of life. To be "vividly stimulated," "interested in a high degree," "plunged in my own interesting labours," are frequent and favourite expressions, and leave an almost exhilarating impression on the reader of these remarkable recollections. For the rest, the lively description of the beginnings of things which form the backbone of our present civilisation, or at any rate of our social and commercial activity, cannot fail to be as absorbingly interesting to the reader as they were to the great inventor.

Notes et Formules d'Électricité Industrielle. By Robert P. Bouquet. (Paris: Bernard et Cie.)

This is one of the handbooks which on the Continent take the place of our so-called pocket-books. It contains numerous tables and formulæ and a mass of more or less digested scraps of information, useful and otherwise, on electrical science and engineering. It is provided with a brief index and a rather long list of errata. It will no doubt be found a very useful book of reference.

THE IMPEDANCE OF MUTUALLY INDUCTIVE CIRCUITS.

BY A. E. KENNELLY.

In an interesting Paper on "Mutual Inductance and Capacity," appearing in No. 2 of the *Physical Review*, and recently read before Section A of the Electrical Congress at Chicago, Drs. Bedell and Crehore discuss algebraically the currents flowing in two mutually inductive circuits containing inductance, resistance, and capacity. It is the object of this article to show that such circuits when conveying harmonic currents can be treated simply and conveniently by the geometrical methods of impedance.

In the *Transactions* of the American Institute of Electrical Engineers for April, 1893, Vol. X., No. 4, p. 173, it is pointed out by the present writer that the distribution of simple harmonic currents in any network of conductors possessing resistance, inductance and capacity, can be determined by the corresponding rules for continuous currents, if definite "imaginary" resistances be substituted for the condensers and self-inductances. Mutual inductances are, however, left out of consideration, and the omission may here be supplied.

If a circuit, a, is supplied by an effective alternating E.M.F. of e_a volts with sinusoidal currents, making $n = \omega 2\pi$ periods per second, and has a "non-ferric" inductance of l_a henrys, a capacity in series of c_a farads, with a total resistance of r_a ohms, the impedance J_a of the circuit may be graphically represented by two rectangular components, namely, a horizontal resistance of length r_a and a vertical "reactance" of length $\lambda_a = \omega l_a - \frac{1}{\omega c_a}$, while by Ohm's law the current in the circuit becomes $i_a = e_a/J_a$ amperes.

Now suppose a secondary circuit b, of impedance J_b, whose components are similarly r_b and λ_b, to become linked with a through the influence of a mutual inductance of μ henrys.

The first tendency will be for the current i_a in a to set up an induced E.M.F. in b of $\omega \mu i_a = e_b$ volts, which would give rise to a current in b of $i_b = e_b/J_b$ amperes. But this current when flowing would act from b as a primary on a as a secondary circuit, and set up in a an induced E.M.F. of $\omega \mu i_b$ volts, the current from which would be superposed upon i_a, and would in turn react upon the circuit b. The successive modifications in primary and secondary currents would cause them to rapidly converge towards values so adjusted that the current in each circuit obeys Ohm's law after the E.M.F. induced by its neighbour has been taken into account. Calling i_A the finally modified or resultant current strength in the primary circuit, i_A would be established by the E.M.F. e_a unaided if the primary impedance J_a were altered to J_A, such that $i_A = e_a/J_A$. This virtual impedance J_A is obtained from J_a by increasing the resistance component r_a by $n^2 r_b$, and diminishing the reactance component λ_a by $n^2 \lambda_b$, where $n = \frac{\omega \mu}{J_b}$. The primary current is thus

$$i_A = \frac{e_a}{J_A} = \frac{e_a}{\sqrt{(r_a + n^2 r_b)^2 + (\lambda_a + n^2 \lambda_b)^2}},$$

the induced secondary E.M.F.

$$e_B = \omega \mu i_A,$$

and the induced secondary current

$$i_B = \frac{e_B}{J_B} = \frac{\omega \mu i_A}{J_B} = n i_A.$$

The effect of bringing the circuit b into relation with a is to modify the impedance of the primary a, and to establish in b the E.M.F $\omega \mu i_A$.

An equivalent to this result was first given by Maxwell.

As an example of the application of this process, the case represented in Fig. 1 of a primary and secondary circuit may be considered. Condensers are inserted in each circuit for the sake of generality, but their removal may be effected when requisite by assuming that in the formula their capacity is infinitely great.

In the primary circuit a let the total resistance $r_a = r_1 + r_2 + r_3 = 20$ ohms, the capacity $c_a = 10$ microfarads $= 10^{-5}$ farad, the inductance $l_a = (l_1 + l_2) = 0{\cdot}2$ henry, the effective E.M.F. $e_a = 100$ volts.

In the secondary circuit let the resistance $r_b = 50$ ohms, the capacity $c_b = 10$ microfarads $= 10^{-5}$ farad, the inductance $l_b = 0{\cdot}05$ henry.

Let the mutual inductance be $\mu = 0{\cdot}05$ henry and the frequency $n = \omega/2\pi = 159{\cdot}15$, so that $\omega = 1{,}000$.

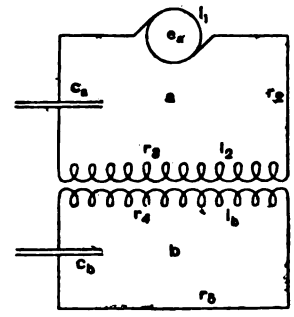

FIG. 1.

Then Fig. 2 represents the corresponding impedance diagrams for the primary and secondary circuit. O E = 20 ohms, O B is the primary inductance speed $\omega l_a = 200$, B D the capacity-speed-reciprocal $\frac{1}{\omega c_a} = 100$, laid off downwards, so that E D gives the normal impedance $J_a = 102$ ohms. Similarly S R represents the secondary impedance $J_b = 70{\cdot}7$ ohms, the reactance λ_b being here

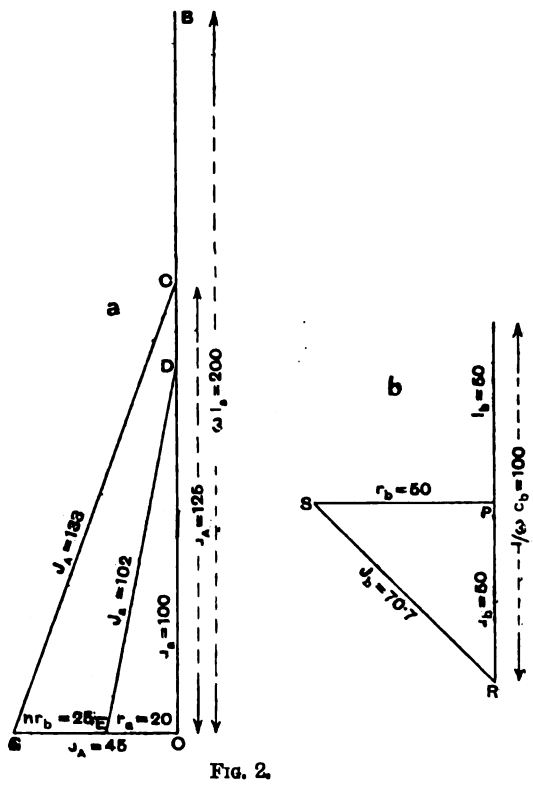

FIG. 2.

negative, by reason of the excess of capacity-speed-reciprocal over inductance-speed. The factor n^2 is now

$$\left(\frac{\omega \mu}{J_b}\right)^2 = \left(\frac{1{,}000 \times 0{\cdot}05}{70{\cdot}7}\right)^2 = 0{\cdot}5,$$

so that according to rule the primary resistance is increased by $n^2 r_b = r_b/2 = 25$ ohms to G. Half the secondary reactance is now deducted from the primary reactance, but since λ_b is negative $-n^2 \lambda_b$ is positive, and the primary virtual reactance is increased to O C = 125 ohms. G C therefore represents the virtual impedance $J_A = 133$ ohms, of the primary circuit, in which the current will be $i_A = e_a/J_A = 100/133$ 0·752 ampere, whence the secondary E.M.F. will be $\omega \mu i_A = 37{\cdot}6$ volts, and the secondary current $e_B/J_b = 37{\cdot}6/70{\cdot}7 = 0{\cdot}532$ ampere.

Digitized by Google

To illustrate the ready application of this method to more complex cases one more example may be permitted.

Fig. 3 represents a simple harmonic E.M.F. acting upon the primary circuit of an induction coil shunted by a condenser.

The secondary circuit of the coil is closed through a resistance. In order to determine, by the ordinary algebraical process, the currents and voltages in the various branches of this system, a determinant of the sixth order would have to be solved. By the graphic methods of impedance treatment the solution is readily obtained, and a check is kept upon the arithmetical work, even if the diagrams are subordinated as mere guides to their equivalent numerical operations. The first step is to find the impedance of the secondary circuit, then to modify the impedance of the primary branch B N K G for the mutual inductive effect; next to find the joint impedance of this modified primary branch and the condenser in parallel; and finally, to sum this joint impedance with that of the main branch B D G, for the total effective impedance

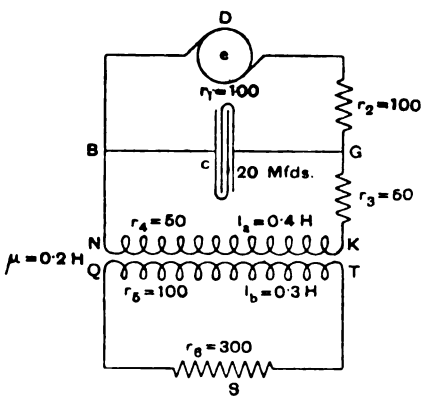

Fig. 3.

of the main circuit. This, divided into the effective E.M.F., gives the main current by Ohm's law, and the various branch current strengths immediately follow.

Let e = 1,000 volts effective, at $\omega = 1{,}000$ or $n = 159{\cdot}1$ ∽.
$r_1 + r_2 = 200$ ohms.
$r_3 + r_4 = 100$ ohms.
$r_5 + r_6 = 400$ ohms.
l_a = 0·4 henry $\therefore \omega l_a = 400$ ohms.
l_b = 0·3 henry $\therefore \omega l_b = 300$ ohms.
μ = 0·2 henry $\therefore \omega \mu = 200$ ohms.
c = 20 microfarads. $\therefore 1/\omega c = 500$ ohms.

Then diagram b of Fig. 4 represents the impedance of the secondary circuit, O P being the resistance of 400 ohms to scale, O R the reactance of 300 ohms, and P R the impedance J_b of 500 ohms. The factor of mutual influence $\left(\frac{\omega \mu}{J_b}\right)^2 = n^2 = 0{\cdot}16$ so that the increments of the primary branch components are $0{\cdot}16\ r_b = 64$ ohms, and $-0{\cdot}16\omega l_b = -48$ ohms. Diagram a shows the impedance of the primary branch B N K G, and its modification under mutual inductive effect from Y V to Z W = 388·3 ohms. Diagram g shows the vector sum Z′ R′ of the vector reciprocals of Z W and of the condenser impedance, to a conveniently altered scale, while the reciprocal of Z′ R′ is Z″ R″ in diagram h = 878·7 ohms to the original scale. This is the impedance of condenser and coil in parallel. The impedance ($r = 200$ ohms) of the branch B D G is now added vectorially in diagram h, bringing the impedance of the main circuit to A R = 1071·7 ohms.

The main current in B D G will therefore be 1000/1071·7 = 0·933 ampere. The drop in B D G will be 0·933 X 200 = 186·6 volts. The effective voltage between points B and G = 813·4 volts. This voltage acting upon the condenser impedance of 200 ohms establishes in the condenser an effective current of 813·4/200 = 4·067 amperes. The effective impedance of the modified primary coil branch B N K G is 388·3, and the current it receives 813·4/388·3 = 2·1 amperes. The E.M.F. in the secondary circuit is this current multiplied by $n = 0{\cdot}4$ or 420 volts, and the current strength in the secondary circuit is consequently 420/500 = 0·84 ampere.

A current of less than one ampere in the supply circuit thus supports a current in the primary winding of the coil of more than two amperes, with the assistance of the condenser at what may be regarded as the receiving end of the line.

By this method any network of circuits containing resistances, capacities, and self or mutual inductances under the operation of simple harmonic E.M.F.'s can be treated up to any reasonable degree of complexity with little difficulty, when the corresponding direct algebraical process would be prohibitively laborious. If the E.M.F.'s may not be regarded as sinusoidal it may be possible to analyse them into sinusoidal components, to then treat these separately

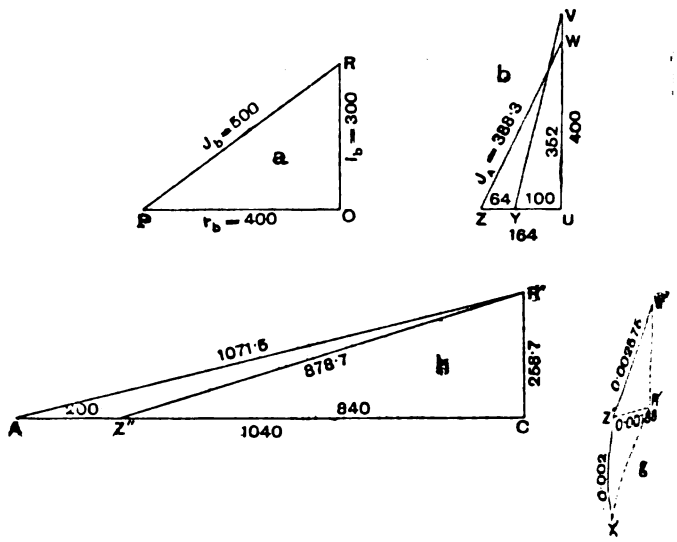

Fig. 4.

and afterwards sum their resulting currents geometrically. The phase of each current can be readily found from the impedance diagrams. Hysteresis in the induction coils and condensers is for the present ignored, which will no doubt limit to a great extent the practical application of the system; but it is at least of some advantage to possess a method which brings harmonic-current circuits almost on a par in simplicity with continuous-current circuits, and under the direct application of Ohm's law by geometrical extension, even if the secondary influences of iron have to be at present omitted or left for secondary consideration.

THE "AJAX" LIGHTNING ARRESTER.

A novel form of lightning guard for attachment to electric light and power circuits has recently been brought out by Mr. R. W. Blackwell. This is known as the "Ajax" lightning arrester, a general view of which is shown in Fig. 1. The arrester is constructed on the magazine principle, being composed of a charge of 10 or more separate fusible lightning guards, which are designed to come into operation successively. Each flash of lightning is earthed through a single guard which it fuses, and by the act of fusing the guard it causes a new guard to be placed on the circuit, ready for the succeeding lightning flash. A single fusible guard is shown in Fig. 2, and consists of a pair of fine brass wires, 2¾in. long, made to lap each other three-quarters of an inch at their near ends, with $\frac{1}{16}$th of an inch air-gap between them. A short piece of glass tube is sealed over the lapping portion of the wires, to keep them clean and dry. By connecting the outer ends of this guard the one to the line and the other to earth, a simple and cheap arrester is produced. This is accomplished by providing each fuse with two soft rubber plugs, so spaced by the knots in the wires that the rubbers will fit tightly into the porcelain cover of the arrester box (*see* Fig. 1), allowing the free ends of the wires to project through the cover into the channels of the porcelain box containing the carbon termina-

Digitized by Google

rods; but they do not come into contact with the latter. Loose pieces of carbon, made like small wedges, connect the free ends of the upper fuse to the carbon terminals. In this position the arrester is ready to be placed in circuit.

In operation, the atmospheric discharge finds a free passage to earth, except one small gap of $\frac{1}{20}$th of an inch, which is promptly bridged. The discharge starts an arc, which short-

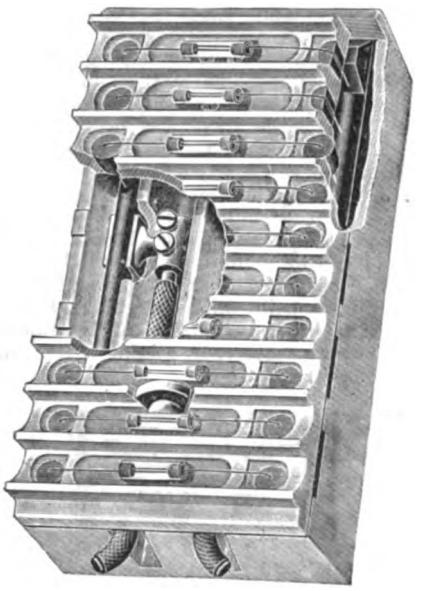

Fig. 1.

circuits the line at this point, and the sudden rush of current is sufficient to entirely consume fuse No. 1, and the carbon wedges immediately drop to the free ends of fuse No. 2, bringing it into operative position. Ten fuses are considered enough to protect any locality during a single thunderstorm, after which the arrester should be examined, and any missing fuses be replaced with new ones.

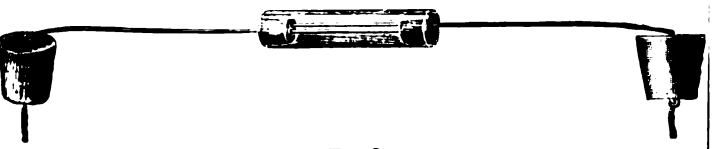

Fig. 2.

New fuses may be readily inserted by removing the cover, which, after the arrester is refilled, is replaced with the carbon wedges connecting the top fuse, as before. Since the operation of this arrester depends upon a short circuit, it is designed only for circuits using a ground return or a ground wire, and is especially adapted for tramway practice, being applicable to the pole line, cars, or power-house.

THE ARTIFICIAL LIGHTING OF WORKSHOPS.*

BY BENJAMIN A. DOBSON.

In manufacturing districts the use of artificial light is of considerably greater importance for work of all desciptions than it can be elsewhere. Whether the work be fine or coarse, delicate or bold, a better light is needed than for work which does not come under the head of manufacture. In Lancashire the staple industries of engineering, machine-making, spinning, weaving, bleaching, and dyeing, are mainly established in certain centres; and with them is invariably associated in the surrounding district the great coal industry. Although Lancashire coal has a number of excellent qualities, yet it is one that makes the most smoke of any. A large portion of the manufacturing industries, great and small, date from a number of years back, when smoke-consuming and smoke-preventing apparatus had not yet been devised; and many of the factories are working at the present day under pretty much the same conditions as when they started. Hence the atmosphere in all manufacturing towns in Lancashire is heavily charged with unconsumed carbon, producing an excess of cloud and fog, which, while inducing an excess of rain, acts also as a screen against the rays of the sun, and thus does a double injury to the neighbouring agriculturist, the producer of the country's native wealth. A circle of 30 miles radius around Manchester is said to include a larger population than an equal circle around any other place in the world; and within this circle, about 12 miles north-west of Manchester, lies Bolton, the town with which the author is best acquainted, where all winds, except the west and north-west, bring the surcharged atmosphere from other manufacturing districts, producing at any season of the year, if the wind happens to be slight, a sky ranging from dull lead to dark brown. For four years in succession it has occurred at the writer's works, that on June 21st, the longest day, the gas in every room, amounting to nearly 7,500 jets, has had to be lighted by 11 o'clock in the morning, and has remained lighted until work ceased; and this has occurred also in other towns, and in weather that ought to have secured abundant sunshine. To such an extent does gloom prevail that in clear weather the effect of bright sunlight becomes even distressing to the eye-sight, simply from the rarity of the contrast.

Requirements for a Well-lighted Workshop.—Firstly, the light, if artificial, should be sufficiently intense to give the power of clear and natural sight over any portion of the work. For enabling the work to be performed with ease the light should evidently be arranged to produce as nearly as can be the effect of natural sunlight. The light of the sun is diffused by the atmosphere; and unless its entrance is limited in extent, such shadows as it may produce are only natural shadows, so natural that the eye has no difficulty in following detail in any visible part. In this respect therefore artificial light should as far as practicable imitate the best natural conditions. Secondly, the light should be so diffused as to avoid casting shadows, or placing any one portion of the work in too great relief, as compared with the general tone of the whole. If the work were being done in front of a window which faced the sun, a certain portion of it would receive an undue amount of light, and give a false idea alike of size and distance, owing to the contrast of the overlighted and underlighted parts. This might be a natural light, but would nevertheless be improper. Thirdly, the light should be of such a character as to have no tendency to injure the sight by a blinding glare. This remark applies either to a good gas-flame or to the electric glow-lamp, from both of which the light is well diffused; the rays, being all comparatively weak, are easily diverted and thus distributed. But the effect of having either a bright gas-flame or the still brighter glowing wire before the eyes is exceedingly fatiguing and destructive to the sight, and in combination with the dust of workshops makes it a wonder that ocular diseases are not more common than they are. Fourthly, the light should be of such a character as to leave the atmosphere free from noxious emanations. Any kind of natural or electric light will fulfil this condition. The artificial light that most infringes it is gas, which varies much from town to town, and even in the same town from time to time; but it is generally so impure as to be deleterious to health and comfort in the products of its combustion, which is always more or less incomplete. Fifthly, the light should not unduly raise the temperature of the room in which it is employed. If, on a hot day, a gas burner has to be lit for every person in a crowded workshop, as has to be done in certain manufactories, the combustion of so much gas affects the temperature greatly, and thereby produces lassitude among the workpeople, together with various ailments which are almost in proportion to the amount of gas consumed. Sixthly, the light should be simple and capable of easy control. The whole arrangement should be so contrived that nothing but the simplest knowledge and experience are required for turning the light on and off. This implies, of course, both a central control and also various points of sub-central control. Seventhly, the cost should be kept within such limits as will render the light practicable at the present day for those who have to make their livelihood in their special trade in open competition with the rest of the world.

Electric Lighting by Inverted Arc-Lamps.—Some years ago, while engaged in visiting and examining certain mills on the Continent, the writer was much struck with a mode of lighting which he then saw for the first time. This consisted in the use of electric arc-lamps of from 1,600 to 2,000 c.p., suspended in a white enamelled reflector at a certain distance below the whitewashed ceiling of the mill. The first he saw was of 2,000 c.p., and thoroughly lighted a large room of about 40ft. square with light sufficient to see to pick up a pin off the floor. The walls of the room, as well as the ceiling, were whitewashed. The light had a sort of bluish tinge, and looked like bright moonlight, but with much greater illumination and entirely without shadows. This appeared so striking that he made a few experiments at once, and found that it was possible to see into the interior of the machines, and even underneath them, in a way that up to then would have seemed incredible; and

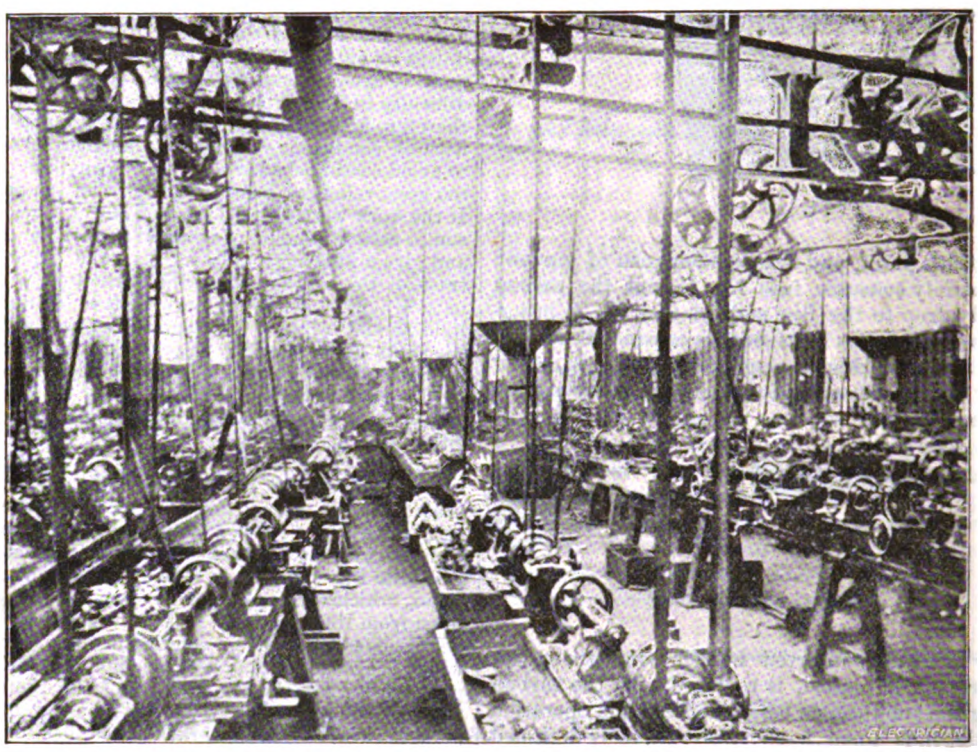
* Abstract of Paper read before the Institution of Mechanical Engineers, on Wednesday, Oct. 25, 1893.

Digitized by Google

further, that it was not possible to make a shadow of any description, even when holding a hat only 2in. above the floor: all that could be seen in the centre of the covered part was a comparatively slight deepening of the shade. In other departments of the factory he found the same plan equally effective, and the diffusion of light so complete as to be astonishing.

Incandescent Glow-Lamps.—At that time the author's firm were engaged in replacing gas by incandescent glow-lamps on the Edison-Swan system in a large machining room at their own works, which is 345ft. long by 76ft. broad and only 12ft. high, containing 239 machines tended by 200 workpeople in the area of 26,220sq. ft. The exigencies of trade had required that annexes should be constructed almost all round the building, thus further diminishing the amount of natural light that could gain admission. Along the whole of the centre of the shop, for a breadth of some 50ft., gas was burning day and night; and in the close muggy weather of autumn and the fog-laden days of hot summer, the atmosphere of the room became most oppressive, in spite of the best ventilation by Blackman propellers; even at six o'clock in the morning, on entering the room, the smell was most objectionable. It was noticeable, too, that an undue proportion of the men suffered from diarrhœa, which was in fact a standard complaint, and furnished the constant explanation for absence from work. Although sometimes this was simply an excuse, there can be no doubt that the exhalations caused by the imperfect combustion of a gas not absolutely pure will suffice to explain the possibility of a large number of men being affected thereby. The incandescent glow-lamps, each with its own switch, and covered with a wire guard, were attached to the gas brackets, which for this purpose were left just as they had been. Within a week of the application of these lamps, the importance of the third requirement, with regard to glare, was amply proved; for nearly every workman had devised a shade of one kind or another, some of white or brown paper, some opaque, and some translucent. No better device than this has been found; it does not look neat, being simply a makeshift; but it answers the purpose, costs nothing, and is applied in a moment. The results of the alteration were curious; the atmosphere was improved, the heat considerably diminished, diarrhœa as a general complaint ceased, and was at first succeeded by bronchitis, which, however, was found to be of a temporary nature, and disappeared as soon as the workpeople in that room had become acclimatised.

Nevertheless with the result of this lighting the author was not satisfied. The shop was as dark and gloomy as with the previous gaslights. The number of lamps broken by accident and by carelessness was so great as to become a serious consideration, their price being out of proportion to their actual cost, and no allowance being made in regard to royalty in replacing broken lamps which had already paid royalty. The writer then made two further journeys to the Continent, in order again to examine the plan of the inverted arc-lamp; and on the first occasion returned more favourably impressed than before. The second journey was therefore made with the view of going more thoroughly into the details, and of concluding arrangements for conducting a trial of the plan in his firm's establishment. On this occasion he had the opportunity of examining a large weaving shed at Ruysbroek, near Brussels, on a dark winter night. The dynamo was driven from the main engine of the mill, and was a fine piece of work. Corridors lighted by incandescent lamps led thence to the vast weaving shed, which had the usual roof containing glass panels almost upright facing north, with a plastered ceiling sloping southwards from the top of each glazed panel, and lighted from an inverted arc-lamp in each bay between the pillars. The impression upon entering the doorway was that the large room was brilliantly lighted by the mid-day sun; no glare, no flames to be seen, but a golden light pervading the whole of the vast enclosure; the colour of the hair, complexion, and costumes of the workwomen perfectly distinct; under the looms not the slightest trace of shadow. In fact the result attained was an absolutely perfect ideal light for textile work. The bluish tinge of the arc light itself, when lighting direct, is more apparent than real, because it does not prevent the most delicate shades of colour from being appreciated. If, however, it is considered disagreeable or undesirable, it can be altered, as it was in this particular weaving factory, by mixing a trace of yellow with the ordinary whitewash; the ceiling is then still white, but the apparently bluish tinge is eliminated.



Workshop Lighted by Inverted Arcs. (From a Photograph taken at 10 p.m.)

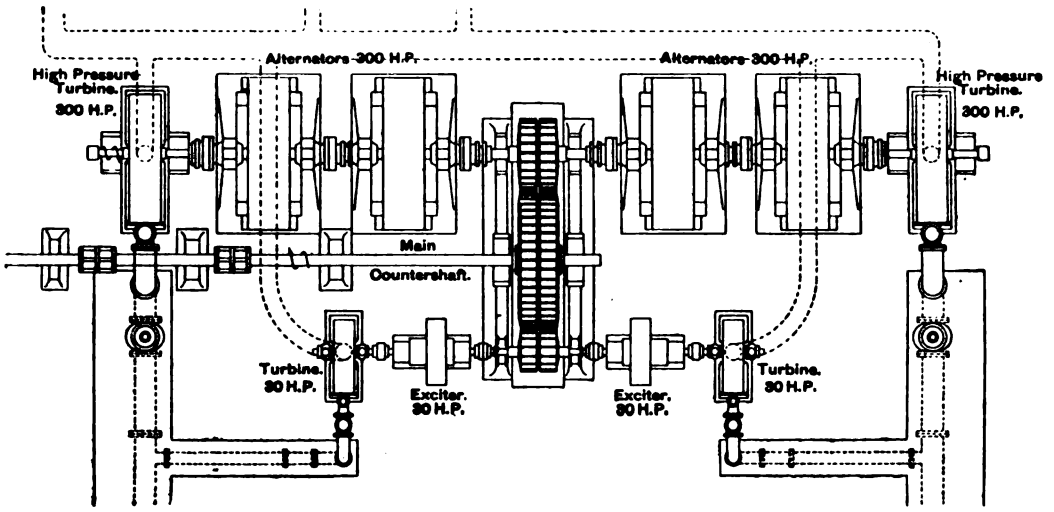
The result of this visit was the application of four inverted arc-lamps in the large low machining room at the writer's works. Over 50 tons of castings are daily taken in and out of this room; and there must be at least 300 tons of castings of various sizes and descriptions, in progress of treatment, stacked and piled in different places on the floor; there is therefore all the more necessity for good lighting in order to avoid accidents. The darkest portion of the shop was chosen, and the four arc-lamps were placed in approximately the best positions for lighting a certain area. The ceiling not being plastered, it was considered advisable to nail up to the joists light scantlings, which were afterwards white-washed. These lights have now been running almost day and night for about two years, and with unqualified success. The four arc-lamps have replaced twenty-six glow-lamps; but whereas each glow-lamp lighted up its own work only and a few inches around, the whole of the area lighted by the four inverted arc-lamps is bathed in a gentle temperate light, absolutely equal in all parts. This was encouraging, as an arrangement of this description involves a heavy expenditure; and it was therefore considered advisable to have further experience before going more largely into it. Moreover, this plan of lighting would not always be applicable. If the ceiling were very low it would scarcely be practicable, because the arc lamp must

Digitized by Google

hang a certain distance below the ceiling and still leave head room. Also there are places where the amount of light required is so small that it would be injudicious to go to the expense of applying these lamps, which are capable of so much more duty. It was determined, however, to make an experiment on a practical scale at the author's works, and with this object to apply inverted arc lamps for the lighting of a three-storey building with large attic floor above, the latter being used as an iron and wood pattern-room.

THE ZÜRICH ELECTRIC SUPPLY.*

This station has been working since August, 1892, and is carried out on the alternating-current system by the Maschinenfabrik Oerlikon. The plant contains features of much interest. Power is derived from the Letten waterworks, where the falls of the River Limat are used for purposes of water supply and power transmission. The falls provide about 1,000 H.P. derived from 10 Henschel-Jonval turbines, and nearly 300 H.P. is used in pumping water for the town supply ; about 250 for a rope-transmission for industrial purposes (shortly to be abandoned), and about 400 H.P. are available for electric lighting purposes ; but since this is not enough for the 30,000 lamps for which the station is designed, the turbines are assisted when necessary by steam engines.



Plan of Electric Light Station at Zürich.

The accompanying plan shows the arrangement of the new electric light station. Under the old arrangement the ten turbines arranged two and two (as seen on the left of the figure) drove in parallel along main countershaft at 100 revolutions per minute by means of toothed gear wheels. Two new turbines (in the middle of the figure) have been added, each giving a minimum of 175 H.P., gearing like the others on to a prolongation of the main countershaft. This prolongation carries at the further end gear wheels as shown, driving on one side a countershaft at 200 revolutions, to which the alternators can be coupled by rigid couplings ; and on the other the exciters at 400 revolutions.

On either side of the gearing are two alternators and an exciter, with a high-pressure turbine of 300 H.P. and another of 30 H.P., capable of being coupled to alternators or exciters respectively. These turbines are automatically regulated by centrifugal regulators, and are also capable of hand regulation. One 300 H.P. turbine and two 30 H.P. are at present running.

Steam engines have also been added as reserve power, helping the low-pressure turbines and gearing on to the main countershaft. Three Galloway boilers (two already set, each with 1,100 sq. ft. heating surface and 120lb. pressure, feed two compound engines, one installed), making 76 revolutions and delivering 300 H.P. They are set opposite the new low-pressure turbines.

As will be seen from the plan, the dynamos can be driven either from the high-pressure turbines or from the main countershaft ; the latter, again, either from the low-pressure turbines or the engines, and either together with, or independently of, the pumps. The mechanical couplings of the dynamos are arranged so that a dynamo can be switched in in five positions corresponding to the corresponding points on the current curves of the two machines.

The electrical part of the installation comprises at present two alternators and two exciters. The former are of the well-known Kapp type, and are of 300 H.P. each. The fields are in the form of a massive casting with 30 projecting poles. The armature is of the well-known pattern. The field castings are mounted on slide rails, give easy access to fields, armatures, and to all joints and couplings. The machines give 2,000 volts and 100 amperes at 200 revolutions per minute the frequency is 50 ∿. The exciters are Manchester-type machines. They give 100 volts 200 amperes at 400 revolutions.

The switchboard is remarkably simple for so large an installation. Hand and automatic regulation is provided. The mechanical coupling of the alternators ensures their running perfectly in parallel, as a machine cannot be thrown into gear except in a position in which it is in step with those already coupled to the omnibus bars.

The system of mains is very original. From the station two main cables run direct to the distributing centre in the middle of the town. The loss of volts up to here at full load is 5 per cent., and the regulation at the station is such as to keep the pressure at this point constant. From this distributing centre direct cables without any branching lead to the transformer stations ; these distributing cables have a drop of 1 per cent. at full load. The transformer stations convert the 2,000 to 200 volts, a three-wire system of secondary distribution being used. There are seven such transformer stations at present in use, containing transformers of 20-kilowatt output each. A special set of conductors is used for the arc lighting, and six lamps in series are placed across the 200-volt mains. 9,000 lamps (8 c.p.) were use in April last.

DIRECT-CURRENT DYNAMOS OF VERY HIGH POTENTIAL.*

BY F. B. CROCKER.

This treatment of the subject is in no sense a formal Paper, being merely a note of some experimental results which I have obtained from two dynamos with very high potential, and it is well, I think, to define what I mean by that expression, which is in some doubt. By very high potential I mean from 5,000 to 11,000 volts. Machines of this character have received comparatively little attention, either from scientific experimenters or practical engineers. Considering these machines historically, the first fact that meets our attention is that there exists a general and deeply-rooted idea that direct-current dynamos of very high potential are not at all practical. This unfavourable opinion is particularly strong in regard to the use of such machines for the transmission of power for any considerable distance ; in fact, such a system is considered to be almost out of the question. The actual historical and practical facts are that the high-potential direct-current machines were more extensively and successfully operated when the dynamo first came into general use about 1880 than any other type, either direct or alternate. Furthermore, their number and size have largely increased, and the voltage at which they can be practically worked has been steadily raised until we now have about 60-light arc dynamos of the standard size on large machines generating about 3,000 volts, or 10 amperes. Arc dynamos of 90-light capacity are also regularly made by several manufacturers, and 120 or even 125-light machines are built and used. I happen to know of one station where there are four arc dynamos rated at 125 lights, which run every night with a load of from 100 to 105 lights. These machines must have force to generate about 5,000

* Address before Section C, World's Electrical Congress, Chicago, August 24, 1893.

Digitized by Google

volts each. No great practical or other difficulty is found in operating arc machines, except that of danger to persons; but this is merely due to the high potential, and does not depend very much upon the type of machine or character of current. Nevertheless, when it is suggested to use direct currents in the transmission of power, we are told that nothing over 1,000, or at the most 2,000, volts is at all practical. Why this discrepancy between the 5,000 volts, which are practically used in arc lighting, and the 1,000 or 2,000 volts that are considered the limitation of such machines for power transmission? Perhaps the first answer to this question would be to say that the current is limited; that when you have 5,000 volts you cannot have more than 10 amperes, and if you want more amperes you must have less volts; consequently the number of watts, which, of course, is the entire question in power transmission, is limited. For example, the machines which I cited, and which are in practical and successful use, are 5,000 volts E.M.F, generate only 10 amperes, and consequently have a capacity of 50 kilowatts, which is a small power, comparatively speaking, for power transmission, but is sufficient for ordinary arc-lighting circuits. That, of course, is a fairly good explanation of why such machines are not applicable to power transmission. But is there any such limit as 10 amperes to the current? I myself always look with very much suspicion and doubt upon any such arbitrary limit as that. Experience has shown me that those arbitrary limits are usually imaginary. Now, it is a fact, however, that should be added to this historical consideration of the subject, that numerous attempts have been made to employ such machines for power transmission and other purposes, and it cannot be said that those attempts have been successful; in fact, it can be said that they have been unsuccessful, but there again we have merely the negative of it. Now, when we come to the actual construction of such machines, and that is really the only substantial point that I can bring before you, I have actual results, although I cannot say that there is any particular feature of such machines which is radical or which will insure their successful operation. The first point, of course, is insulation. That must be above suspicion. The ordinary limit of one megohm of insulation is simply nothing for such machines. One megohm of insulation resistance, with a voltage of 10,000, would give 1/100 of an ampere and 100 watts; consequently the machine insulation would be rapidly heated up and destroyed; therefore, you must realise that a megohm, or even several megohms, is no insulation at all for such a machine. It should be at least 1,000 megohms, which is number one, in fact. The next point is the commutator, because, although the commutator might be considered the first point, as a matter of fact we must have the insulation before we can operate the machine at all, even for a few moments. The commutator, of course, must have a number of sections. It must have a considerable thickness of mica insulation between the bars, more than is ordinarily employed; I should say a full sixteenth of an inch. On the end of the commutator, where you get much more than the ordinary voltage between the bars, you require very much more thickness of mica insulation, or some other insulation, than is ordinarily given.

The next point is the material for brushes, and I have found in that particular feature the most peculiar and important differences. In the first place I consider that it is impossible to run an ordinary mica insulated commutator with copper brushes at that potential, the reason being that this film of copper which is worn off of the copper brushes by the mica is a sufficiently good conductor at that E.M.F. to carry many watts. At an E.M.F of, say, 500 volts, we have no such difficulty, because, even if we use common brush connections, the film of copper that is rubbed on to the surface of the mica would not carry sufficient watts to cause any trouble; but at 10,000 volts, with a total E.M.F. in the neighbourhood of 100 volts between the bars, the amount of copper, even although it is an almost infinitesimal film, is sufficient to carry, as I say, many watts. Now, I have found that with a potential of only 5,000 volts, which I have experimented with, copper brushes could not be used for half a minute; that the copper would work off on the mica and immediately produce a ring of fire all around the commutator. Naturally one would use carbon brushes in such a case, because the current is very small, comparatively speaking, and there is no reason why we should not use carbon brushes. When you come down to the carbon brushes, I have also found that the hardened carbon is better, for the reason that it does not produce a deposit or layer of carbon on the commutator to produce the same effect which the copper does, but not to the same degree, because carbon is a much poorer conductor than copper; therefore carbon brushes, with a comparatively small area of contact and a fairly good pressure, not very great, but sufficient to ensure good contact, seem to be the proper working conditions.

The machines I have actually constructed are two. One was a small machine of 1 H.P. capacity, and the armature was a fluted armature. Some persons may think that is exactly wrong, but the results do not seem to show that it was. It was very perfectly insulated with mica and wound with double silk covered wire. The potential of that machine was intended to be 5,000, and I have succeeded, by slightly raising the speed, in getting 5,500 volts out of it. It had only 32 commutator bars. That machine is not, of course, a practical machine, but it did run for hours at 5,000 volts, for an hour and a-half at 5,500 volts, and several times without any difference.

The next machine, which is a much more practical machine, was of 5 H.P. capacity, and designed to generate 10,000 volts. It did generate 10,000 volts at a little below the calculated speed, strange to say, and gave 11,000 volts at about the speed it was designed for, which was 1,800. This machine had 108 commutator bars, a much more practical number for such a voltage. The current of that machine was intended to be between three and four-tenths ampere, which gives about its capacicy. It must be remembered that these machines did not give their full capacity, owing to the fact that the wire is extremely small, and therefore the percentage of copper in the winding is small. The winding is largely made up of silk, consequently the capacity of the machine is reduced by that fact. That is inherent in any machine wound with extremely small wire. The current actually obtained from these machines is in the neighbourhood of their rated capacity. It would be unfair to myself and to you to deny the fact that there is a spark when you approach the current capacity of the machine, and I think at the current capacity the spark would be too great.

Now, as to the application of these machines, I would say that the purposes to which I have applied them have been ordinary experimental work. For example, one of these machines at 3,000 or 4,000 volts will run a Geissler tube very beautifully. It will produce any other of the so-called electrostatic effects, that is to say, effects produced by very high potential in small quantities. It will, for instance, act very much like an electrostatic machine or a friction machine. It will cause one of these electrical flyers to revolve. In other words, you can get all the electrostatic effects similar to this potential from an ordinary frictional machine.

Another purpose to which the machine is applicable is testing of insulation, and, in fact, that is one purpose for which I made it. It is a very good way to test insulation. You will immediately ask, why not use a high potential transformer as being more convenient and not having a commutator? I answer that by saying that I do not think that is the same test. If the wire is exposed to a direct-current strain, I do not think an alternating-current test is proper. If a wire is subjected to a direct-current strain, it should be subjected to a direct-current test. If it is subjected to an alternating-current strain, it should be subjected to an alternating-current test. The other application is, of course, power transmission, and that will be discussed hereafter, and I would say that, of course, it is not necessary to have the total voltage generated by one machine. In any plant no one dynamo should constitute more than a comparatively small fraction of the total plant, and if you have five dynamos in a central station or power transmission station, there is no reason why they should not be connected in series as well as in parallel, and if you want five machines, as I think you do, in order to guard against the trouble from break-downs—five to ten machines—then you can easily connect them in series and subdivide the voltage just to that extent. Each machine can generate a few thousand volts, two to five, and you could get the total voltage by the proper series connections of several machines.

THE RETURN CIRCUIT OF ELECTRIC RAILWAYS.*

BY THOS. J. McTIGHE.

The progress of the trolly system of electric railways has been so rapid as to become almost bewildering. A multitude of improvements had been added, the necessary result of careful thought and ingenuity of the electrical engineer, and the critical study of the practical railway manager and his assistants. But this has been mostly true of the track and overhead construction and the cars and power equipment. The return circuit has been rather neglected, being largely a case "out of sight out of mind." Originally installed on a basis evidencing immature study, and necessarily without experience, it has been left to shift for itself, or rely upon Mother Earth to open a frictionless path for the nearly exhausted pressure to get back to the power house. Few practical investigations of efficiency have been made, and data are meagre. Yet the return circuit is in some respects as important a factor of the system as the overhead circuit, and a moment's thought will show this to be true. The efficiency of an electric circuit depends upon the resistance of all the parts. We carefully figure out the amount and size of overhead wire so as to bring down the waste of energy in transmitting current to the motors, and we should be logically bound just as carefully to plan out the return circuit. There is this important difference, too, in our favour in the latter case, that, while we must have all copper overhead, and consequently must

* Abstract of Paper read before the Street Railway Association of the State of New York at Rochester, September 20, 1893.

Digitized by Google

struggle with the spectre of cost, when we get in the ground we have a veritable tower of refuse present in the rails, if we but choose to take proper steps to avail ourselves of their valuable help. Track rails are necessary, and they are getting better and bigger for our circuit purposes, and I believe that it will not be long before the absurd and costly supplementary wire will have joined the vast army of discarded expedients, and with it the earth as a permanent part of the return circuit, except in some special cases.

On a wet day in moderate weather the earth is available, and to a very large extent, I believe, considering that with a 70lb. girder rail and double track we have something like 30,000 sq. ft. of earth contact per mile of track. But we cannot rely upon this doing us the same service in long spells of dry weather. Still more, we cannot rely upon it doing any good whatever in severe winter weather. It is not uncommon in this state for frost to penetrate 3ft. in the ground, and to stay there for a whole winter. Under such circumstances the earth-return must go out of our calculation. It is during severe winter that we want to realise our very last watt in the hard pulls we must contend with almost daily. We are told that the strength of a structure is measured by that of its weakest part under the most unfavourable conditions it is to meet. Similarly, in a compound electric circuit the total resistance must depend upon the condition of highest resistance to be met with in any of its component parts. We must plan so as to have our return circuit efficient in the most prolonged summer drought and in the most severe frosts of winter. Ground plates and pipes laid below permanent water level are a refuge in a few favoured localities, but the same can hardly be said of plates and pipes laid in the ground whose moisture depends upon the wayward elements. I have made a large number of calculations as to what should be the total resistance per mile of the return circuit under different methods of the construction of the circuit. In making these calculations I have eliminated the conductivity of the earth, because in average winter weather the earth turns a very cold shoulder to the track. I have eliminated the conductivity of the fishplates, because I believe that under average conditions the comparatively small areas of contact surface are too much oxidised to be of much benefit. I have eliminated all the refinements upon which exact scientific analysis of the subject would insist, such as changes of temperature, moisture, and other conditions which are more or less insignificant in the practical work. I have based the figures on the ratio of 6 to 1 in comparing the resistance of the ordinary soft steel rails with that of our usual commercial copper, and for the latter I have followed the ordinary tables adopted by the wire manufacturers. I have not discriminated between the different assignable values for resistance in the various forms of rail bonds, and have calculated only for the specific metal used in the comparisons, leaving the merits and demerits of the form out of the question. I will refer to the last later on.

In studying the general situation prior to constructing, in the spring of 1891, the railway system of Lincoln (Neb.), I investigated the subject somewhat closely. Though, at the time and under the local conditions, and advocate of iron rail bonds, I was and am yet convinced that supplementary ground wires are an unwise extravagance. I will try to give you the reasons for this belief. In steel rails we usually say that every 10lb. weight per yard means one square inch of cross-sectional area. And every square inch of such area can be brought to terms of copper by dividing by six. The resistance is easily determined, and we thus readily arrive at some important results for comparison. For example, take the average city railway rail as being a 70lb. girder. Its area is substantially 7 sq. in., and the four rails of a double track make 28 sq. in., equal to a single steel bar 4in. thick by 7in. wide. This is electrically equal to a bar of copper having 4·66 sq. in. in area, or, in other words, a copper conductor 1in. thick and almost 5in. wide. With such a magnificent path for our returning current, does it not seem absurd to supplement it with a No. 0 wire, whose area is that of a rod a little over a quarter of an inch square? But when we find the rail resistance per mile to be but 0·0086 ohm, while that of the No. 0 wire is just sixty times greater, the absurdity seems to grow, and it becomes a case of sending a very small boy to do a very big man's work, with the man standing idle on the spot.

A few roads have the supplementary doubled along both tracks, and a few have used slightly larger connected wires than No. 4 B. and S. The West End and the Brooklyn City Railroad Companies laid their tracks with double supplementary copper wires (No. 0, B. and S.), but found them totally inadequate, and now have put up many miles of huge return feeders or mains at great cost. Even these are inadequate. In Brooklyn these return mains (500,000 circular mils) are, when possible, suspended on the elevated railroad structure. I am informed that occasionally the insulation scrapes off and the return main makes contact with the iron work. Heat enough is developed at this leak to soften the insulation for many feet, thus showing that the resistance of the main return is still too high.

I am of the opinion that it would to-day well repay any company using copper supplementary wire to rebond its tracks on, because on the average it would save the cost of such change in one year. And I say the same to those using iron rail bonds.

There is still another phase to this whole question of the return circuit, to which I will briefly refer. I mean the electrolytic decomposition of the rails, when earth is relied upon as the major part of the return circuit. That there is such decomposition must be true. The soil under our paving has for many years been plentifully soaked with ammonia from animal refuse, with ordinary salt in the winters of bygone horse-car days, and to these have been added the leakage from the underground gas pipes. Certainly, such soil, when wet and in contact with the rails, presents all the requisite features of an active depositing bath, there being no dearth of cathodes below. Hence, so long as a considerable current takes place from rails to earth, there must necessarily be a good deal of direct electrolytic decomposition of the rails. Let me take an extreme case. It would scarcely be exaggeration to assume that on Tremont-street (Boston) or Fulton-street (Brooklyn) there is a massing of slowly moving cars, amounting to, say, 100 for one mile of double track. Let the rails used be 70lb. girder, and for the current I should say 20 amperes per car for 15 hours per day would be a fair average. $100 \times 20 \times 15 \times 365 = 10{,}950{,}000$ ampere hours per year. If all this went back to the generator by way of the earth the decomposition of the rails every year would be 7,665,000 grammes, or about 17,000 pounds of iron—nearly eight tons lost from the mile of double track in one year. As the mile of 70lb. rails would only aggregate 220 tons, it would not be many years, at that rate, till the rails would be qualified for a pension for loss of both feet incurred in the service, and in time we might have an illustration of the proverbial "two streaks of rust and a right of way." I have assumed an extreme case, but I have no doubt that there is a considerable amount of direct electrolysis of the rails. Nothing can be done to entirely avoid it, but it can be reduced to a minimum by overhauling the track circuit and giving it as great an electrical value as possible, and it might be retarded by dipping the rails before laying, similar to gas and water mains. In abandoning as much as possible the rather uncertain supposed advantages of the earth-return, we would to a corresponding degree rid ourselves of troubles with gas and water pipes and telephone circuits, and yet would be as safe from lightning as we are at present. If it be admitted, then, that it is desirable to obtain from the track structure as great a conducting power as possible, the question arises, How shall it be done? This at once brings us to the subject of rail bonds, and a criticism of the various types used, with a view of arriving at the best from all points of view. There have not been many types brought out by the manufacturers. Probably the earliest was made of a piece of wire having its ends coiled around two rivets and dipped in solder. This form is still much used, but it is objectionable. By its use four contacts exist at every rail joint, *i.e.*, rail to rivet, rivet to wire, wire to rivet, and rivet to rail. To ensure its position in the rail the rivet must be upset, and this, in a great number of cases, either starts or completely loosens the contact between the rivet and wire. If it escapes this, the constant vibration of the rail, sooner or later, causes loosening of the wire on the rivet. Once looseness occurs, the bond is of little use. Again, the essential nature of such a rail bond precludes the use of any large wire in its construction. Still, many roads have used them, and are still doing so. The wire generally used is No. 4 B. and S., sometimes iron and sometimes copper. Another type which has met with much favour consists of two soft-iron pins with enlarged heads, which are drilled transversely to receive the connecting wire which is upset after passing through the heads. This form is open to the same objections as the previous one, being in three pieces, the integrity of whose contact is almost sure, sooner or later, to be destroyed, whether the intermediate wire is iron or copper. Later on appeared the ingenious and, from a purely constructive aspect, very economical, "channel pin." It met an enormous sale, and it is to-day in extensive use. It requires three pieces, is not capable of riveting in the rail, and its form prevents the pin and wire from completely filling the hole in the rail, and rapid corrosion of contact is inevitable. Being merely driven wedge-like into the rail-hole its stay is not reliable, and by corrosion and continual vibration it becomes loose and almost valueless. There is, too, a tendency for the workman to force the wire against the sharp edge of the hole while driving the pin, thus weakening the wire very materially. It, too, like the rivet-and-wire bond, has a limitation as to the size of the connecting wire. No matter how carefully the mechanics of the job are attended to, we have a mere plug driven in a hole. Another type of rail bond is that composed of a piece of copper wire with cast copper rivets electrically welded thereto on projecting stems the size of the wire. This is an attempt in the right direction, but does not work out in practice. The electric weld is apparently uncertain, the union in many cases under my inspection being so imperfect that it could be broken by hand. The small copper castings exhibit radial crystallisation, making welding difficult. Many also break in applying to the rails, and such happenings destroy confidence.

Digitized by Google

I now come to what is known as the "solid one-piece bond," which has sprung into great favour. It would be disingenuous were I not to announce that this rail bond is a patented invention of my own, but I hope that you will admit that I am trying to view this question from a disinterested standpoint.

This solid, one-piece rail bond is simplicity itself. It is merely a wire with expansion curves at its ends on each of which a heavy shoulder is swaged from the wire itself, so that both the rivet ends thus formed and the intermediate wire are all one solid integral piece. From rivet to rivet there can be no failure of contact, except by forcible rupture or total corrosion, and there can be no failure of contact between bond and rail, because when the rivet end is properly headed up, the connection made is perfectly water-tight and air-tight, and is proof against pounding and vibration. There is no solder required, no parts to shake loose, and there is no restriction in size of wire, as the bond can be made of No. 4 wire, and it can be made of No. 0000, and larger if desired. I suppose the great majority of rail bonds used span around the fishplates, which nowadays are quite long. My belief is that this is a mistake. The 12in. bond has the advantage in the total track resistance of from 40 per cent. to 50 per cent. A 12in. solid bond, with its expansion curves, makes a distance between rivet centres of about 8in. Electrically considered, it does not matter what part of the rail end is used for bonding. The holes can be drilled through the flat "tram or through the floor of the rail, 4in. from the end, just as readily as through the web or stem. There is no difficulty whatever, and I can imagine no type of track construction forbidding the use of short bonds. I have bonded many miles of track in this manner, and used the 12in. bonds and had no trouble. In girder rail I prefer to drill the holes through the flat tram taper ream the holes from above, and deeply countersink; then pass the rail bond up from beneath, and head up the ends till the taper and countersink are completely filled. This method has one great advantage, in allowing every rail bond to be inspected at any time without disturbing the paving. The tracks of the Atlantic Avenue Railroad, in Brooklyn, were bonded in this way with No. 000 copper bonds, 8in. long between rivet centres, and they have given entire satisfaction. Rail bonds should, after being applied, be either heavily coated with shellac and asphaltum, or have a grooved strip of wood filled with asphaltum slipped around while the compound is soft. This will prevent corrosion.

Another important element of the return circuit, in such roads as do not pass the power house, is the main return. Whether earth circuit is used or not there should be a heavy connection from the generator or switchboard by the shortest route to the rails. Such a course is generally adopted, but the size of the conductor is apt to be too small. I have seen several cases of serious inadequacy in this direction, so much, indeed, as to heat the main return. The old rails can be advantageously used for the main return in many cases. When it comes to using a large number of heavy copper wires overhead or underground on the one hand, and on the other hand an equivalent capacity of old rails laid underground, the latter is much cheaper, and can be made entirely durable. The rails can be connected by heavy copper plates by riveting, the number of rivets being equal in carrying capacity to that of the rail and plate. The whole structure can be laid in a wooden trough filled with pitch, and will remain intact for an indefinite period. A one-rail line of this kind, composed of old 60lb. flat or centre bearing rail, is as good as a copper bar 1in. square, or six No. 0000 copper wires.

I am, therefore, led to the conclusion that the best return circuit is that which complies with the following requirements:—

1. Intrinsic resistance, low enough to need no help from earth.
2. Utilisation, to the utmost practical extent of the rails as the return conductors.
3. Rail bonds of the heaviest practicable size.
4. Rail bonds of the shortest possible length, consistent with due allowance for expansion and vibration.
5. Rail bonds made of a single piece of wire with integral rivets.
6. Rail bonds tightly riveted to the rails through holes freshly reamed immediately before bonding.
7. Rail bonds so placed as to permit convenient inspection.
8. Rail bonds protected against corrosion.
9. A very liberal use of heavy cross bonds from rail to rail direct, and in double track, extra heavy cross bonds connecting the two inside rails.
10. An underground main or trunk return from power house to track, and there connected to each line of rails, and low enough in resistance to carry the maximum current with but a nominal drop in potential.

Not one of these requirements is an extravagance, but, on the contrary, their proper application to almost any electric railway in the country would be of immediate and lasting benefit. In new constructions they would be a positive economy in first cost. There is not one of them which cannot be adopted in practice, and it seems obvious that their complete embodiment in any existing road would be immediately noticeable in the power house and eventually in the dividend.

CORRESPONDENCE.

PROF. POYNTING'S STILL MORE MODERN VIEWS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have not yet had time to read Prof. Poynting's articles except in the most hurried manner, and before I reply I must study them with the attention they deserve. Meanwhile you will permit me to thank him for his useful criticisms, and to express the hope that I may be able to utilise some of them in a hypothetical "future edition."

On the face of it I like his improvement of my model by adding to it a set of locomotive bars, as suggested in Article II. I was anxious to show that a current *need* be nothing progressive on Maxwell's theory, and perhaps I overstrained this point and made out that it *was* nothing progressive, thereby making my model more difficult to grasp and less simply consistent with what had gone before.

In Article III. I see he recalls us to the possibility of magnetic energy being potential and electric energy kinetic, instead of *vice versâ*, but this view of the matter has never been wholly absent, and I have felt that several of Lord Kelvin's theories inclined to it. I admit adopting the other as more Maxwellian, and on the whole simpler; but whenever we attain to the ultimate hydrodynamical solution the two views will practically become one.

There is just one point where I am able to say at once that I do not agree with him, and that is his objection to Ampère's theory because of its attribution of perfection to material atoms. I see no reason for postulating any dissipation of energy as occurring in the ultimate atom itself, though every reason for assuming it in an assemblage of atoms. Atoms seem to be perfectly exact in weight and modes of vibration. I say this (in spite of Mr. Crookes's "average" hypothesis) on the basis of Michelson's experiments and Maxwell's gas theory; they are perfect in elasticity (though I admit that this statement is incomplete); and I see no reason why they should not be perfect in conductivity. The recent measurements of Dr. Fleming on the conductivities of metals at temperatures of boiling oxygen seem, indeed, to countenance the possibility of even an assemblage of atoms constituting a perfect conductor if they are sufficiently nearly in contact with each other.

If Prof. Poynting adheres to his antipathy to perfection it will be an interesting position, having important bearings in many directions. Doubtless the question trends in the metaphysical direction, but so does all physics if you push it far enough. We shall have to learn not to be afraid of a reasonable kind of metaphysics if we are to attack fundamental problems.—Yours, &c.,

OLIVER LODGE.

October 24, 1893.

SEARCH-LIGHT INTENSITIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the report on the Electrical Congress of Chicago, in your issue of September 29th I read a remark on the "hundreds of million candle-power" of the World's Fair search lights. Having given the problem of search lights some attention myself, I beg to be allowed to explain a misunderstanding.

These enormous brilliancies of hundred millions of candle-power of large search lights are no exaggerations, but based on actual observation by photometer. But they are not the intensity of the arc lamp, but that of the reflected beam of light. The arc of 150 amperes, and 2cm. to 3cm. crater diameter gives some 50,000 c.p. as average intensity in the angle of 120deg. to 140deg., subtended by the reflector. The reflector collects the light rays and sends them out as a narrow beam, of say, 2deg. diameter. Hereby the area lighted by the arc is reduced in the proportion 120^2 to 2^2, that is 3,600-fold, and the intensity consequently increased—neglecting absorption, false reflection, &c.—3,600-fold giving $50{,}000 \times 3{,}600 = 180{,}000{,}000$ c.p. as the intensity of the narrow beam of light sent out by the reflector. Herefrom it is obvious that search-light intensities are really of the

Digitized by Google

magnitude claimed of hundreds of millions candle-power. Approximately, the intensity in the beam of a search light is the intensity given by an arc of the diameter of the reflector as crater diameter. But such an arc would give this intensity over the whole sphere or half sphere, while the search light gives it only in a narrow beam.—Yours, &c.,

Lynn (Mass.). CHAS. P. STEINMETZ.

ALTERNATING-CURRENT DISTRIBUTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Since the appearance of Prof. Robinson's valuable "Comparisons between the different systems of distributing electricity," I have weekly been expecting the realisation of the prophecy with which you heralded the appearance of that article, namely, that "endeavouring, as he does, to hold an impartial position, he is, of course, sure to be attacked by some alternate-current men." I am afraid this suggestion might lead unthinking persons to the conclusion that one of the recognised properties of alternating currents is to render the advocates of their employment peculiarly liable to irritation whenever they encounter fairness and impartiality in argument. But as a considerable time has elapsed without any expression of opinion from the "alternate-current men" as regards Prof. Robinson's article, such an effect of alternating currents on the nervous system may, I think, pending further investigations, be not unreasonably denied. The seat of irritation is much more probably to be found in the more satisfactory balance-sheets which the continuous-current supply companies have hitherto usually been in a position to issue. The wonderful improvement of the Metropolitan Electric Company, however, in this respect which the past year has witnessed, leads both to the conclusion that this state of affairs may undergo modification in the future, and also that Prof. Robinson's characterisation of the distributed transformer system as "obsolete" may stand in need of some slight alteration. "Obsolescent" would, I think, be a better word to describe the manner in which it is at present usually carried out. The point of view which "alternate current men" who are abreast of the times are most likely to take up in regard to Prof. Robinson's survey is one of surprise that he should have omitted all mention of recent improvements in connection with the system which promise to effect a decided revolution in the efficiency of distribution by separate transformers as compared with other methods, and in particular with the system of transformer sub-stations to which Prof. Robinson very naturally gives preference over the old system of distributed transformers. By attaching to each transformer an automatic switch (as described, I believe, in a recent number of *The Electrician*) so constructed that whenever the secondary circuit is closed (say even through a single 8-c. p. lamp) the primary of the transformer is thrown into connection with the mains, while when all the lights are turned out this connection is automatically severed, the constant day-loss when on open secondary through idle or "magnetising" current is completely eliminated. Prof. Robinson takes the all-year efficiency of separate transformer distribution under the most favourable conditions at 66 per cent. as a maximum—an estimate slightly in excess of that given by Prof. Fleming. We shall not be greatly in error if we assume in a town district, taking the different classes of customers one with another, that the transformers are on open circuit year in year out for 20 hours out of the twenty-four, *i.e.*, that the consumer uses the light for an average of four hours per diem. Again, taking one consumer with another, we may assume that transformers run at about half-load (on the average) during the time the consumer is using the light. Now it is perfectly possible to obtain transformers with a half load efficiency of upwards of 90 per cent., and as the losses due to fall of E.M.F. over the areas in which comparisons with the sub-station system or continuous current distribution can be instituted are practically negligible, the elimination of idle or "magnetising" current in the yearly account means a possible all-year efficiency of upwards of 90 per cent. as against 66 per cent. on the "obsolete" system of distributed transformers left permanently in connection with the mains.

It is not, however, with this obsolete system that the automatic disconnection system has to compete, but, as will be apparent from Prof. Robinson's Paper, with the system of distribution by sub-stations. Let us consider for a moment what degree of efficiency is in this case attainable. Prof. Robinson puts the idle or magnetising current at 1 per cent. of the three-fourths load current. This means that a 25-H.P. transformer takes 142 watts on open circuit. This is an exceedingly low estimate, and I do not think I need fear contradiction from practical men if I assert that most of them would be extremely glad to be able to procure a few 25-H.P. transformers that were as economical. Let the estimate pass, however. What does it work out at? The average time, summer and winter, that the 25-H.P. transformer is on open circuit will, of course, be a good deal less than is the case with separate transformers. In a district in which shops and private houses are fairly equally divided it may practically be taken at 18 hours per diem. At the same time it will be found that only in the case of exceptionally fortunately situated sub-station transformers will the average load exceed one-fourth. With a one-fourth load efficiency of 86 per cent. (a high figure) this gives an all-year efficiency (with an idle current of 142 watts) of 82·6 per cent., which estimate, however, must be further reduced by the fall of E.M.F. on the low-pressure mains. Assuming that the *average* or mean distance of the customers is 100yds. from the sub-station, this will amount to 2½ per cent., and the efficiency of distribution will come out at 80·5 per cent.

These figures are, I think, sufficient to show that an economy of at least 10 per cent. may easily be effected by the automatic disconnection system as compared with the sub-station system. I say at least, for while most station engineers will, perhaps, admit that a 25-H.P. transformer, taking only 142 watts on open circuit, may yet be put on the market, they would probably unanimously declare that they have not yet been privileged to form its acquaintance.

That there would be much to be said for the distributed transformer system, and that its heaviest disadvantage would be removed, if only the transformers could be prevented from taking current on open circuit, is shown by the amount of attention directed by Mr. Swinburne and others to attempts to eliminate the idle current by the use of condensers in shunt. This it is, of course, perfectly possible to do when the right capacity for the condenser is hit upon, though, as Prof. Fleming has pointed out, the loss is in all probability merely shifted from one place to another, while the waste due to the condenser when the transformer is loaded is very considerable. This probably explains the fact that the condenser has not come into practical use, and we may conclude that, if adopted, it would probably diminish the coal bills but little, and would certainly not be in a position to effect anything like the amount of economy attainable by means of the automatic disconnection system.

Some fears were entertained at first that the "rush of current" on cutting in a transformer, to which Prof. Fleming has drawn attention, might have a prejudicial effect upon the insulation of the transformer; but it has been found that the rush never occurs when the secondary is closed *before* the primary. By arranging that this always takes place, the one practical objection to the system has been removed, and nothing now remains to prevent the alternate-current companies from taking advantage of the very considerable economies which it affords.—Yours, &c., R. N. LUCAS.

October 21.

ELMORE'S WIRE MANUFACTURING COMPANY (LIMITED).—A meeting of the shareholders of this Company was held yesterday (Thursday) at Winchester House, London, E.C. No public notice of the meeting being held had been issued, therefore our reporter was not present.

INTERNATIONAL OKONITE COMPANY (LIMITED.)—A meeting of the shareholders of this Company will be held at the Cannon-street Hotel, E.C., to-day (Friday) at 12 o'clock.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The Directors of this Company state that, owing to the critical state of affairs in Brazil, they will be unable to recommend a dividend for the half-year ended June 30th last. They have placed £12,000 to reserve fund, and propose to carry forward £7,679 to the current half-year.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning. New Catalogues, Price Lists, and similar matter should be sent early in the week.*]

The 1893 Edition of "'The Electrician' Electrical Trades' Directory and Handbook" contains over 1,000 pages, several new and handy features having been added. Price 7s. 6d., post free 8s. 3d.; abroad 8s. 10d. *Comparison with any similar electrical publication is specially invited.*

The 1894 Edition is in preparation, and will be published in January next. New names, alterations of addresses, &c., are received at any time, but the Directory blanks and circulars are not sent out until later in the year, in order that the most recent, and consequently the *correct*, addresses *only* shall appear in the book. Full printed particulars can be obtained, post free, from "The Publisher," *Electrician* Office.

"Drum Armatures and Commutators."—This book, which is written by Mr. F. Marten Weymouth, and is the latest addition to *The Electrician* Series, is now ready, and will be sent direct on receipt of the published price, 7s. 6d., or it may be obtained from any bookseller. A prospectus will be forwarded free on application.

Tenders Invited.—*Extension of Time.*—It will be seen by our advertisement columns that the time for sending in tenders for the various contracts in connection with the electric lighting of the borough of Sunderland is extended to Friday, November 17th.

——— The Electric Lighting Sub-Committee of the Corporation of Newport invite tenders for the supply and erection of engineering and electrical plant and apparatus for the equipment of the Municipal Electricity Works of the County Borough of Newport. The plan of buildings, map, specifications, &c., can be obtained at the offices of Mr. Robert Hammond, consulting engineer to the Corporation, 117, Bishopsgate street, London, E.C., on and after Monday, the 30th inst., and tenders must be addressed to Mr. Albert A. Newman, Town Clerk, the Town Hall, Newport, (Mon.), not later than Monday, November 20th. Further particulars are given in our advertisement columns.

——— Tenders are invited for the wiring, provision and fixing of the electric light fittings, &c., for the electric lighting of the Midland Deaf and Dumb Institution, Derby. The specification and forms of tender may be obtained from Messrs. Bramwell and Harris, and tenders are to be in by noon on November 6th.

Bankruptcy.—In the case of William Andrews, electrician, lately trading at 118, Hungerhill-road, Nottingham, the liabilities are given at £495 and the assets at £423, leaving a deficiency of £72. The bankrupt has taken out several patents for improvements in railway signalling apparatus, and a company (the Railway Electric Fog Signal Syndicate (Limited) was incorporated with a nominal capital of £25,000, in £1 shares, to purchase and exploit the patents. The bankrupt has transferred the great majority of his shares to other persons, and now possesses only 900, which he estimates to be worth £225. After making all deductions, his entire interest in the patents is represented by an estimated surplus of £390, but the Official Receiver thinks it extremely doubtful whether this sum would actually be realised. The public examination of the bankrupt is fixed for November 3rd.

The New Incandescent Arc Light.—Under this title the Royal Arc Electric Company, of 143, Liberty-street, New York, are introducing the lamp described by Mr. L. B. Marks before the Chicago Congress, and illustrated in *The Electrician*, p. 503 of the present volume.

Serious Theft of Electrical Plant.—Recently the Cardiff electric light station was broken into, and property amounting to a considerable value was stolen. The property chiefly consisted of exciting fluids which are not usually to be found even in a battery station, and comprised six bottles of champagne, a pint of brandy, *half* a bottle of Scotch whisky, four bottles of hock, besides nine bottles of ginger beer and a quantity of Apollinaris water. In addition, the plant at the Cardiff electric works was diminished to the extent of 25 plates, though it is not clear if these were L-type plates or the ordinary dinner-table article.

Aluminium Solders.—Mr. W. Archibald Briggs, of 87, High-street, Dundee, sends us a circular announcing that, as the result of recent experiments, he is now in a position to offer a more fusible solder than hitherto, suitable for the very thinnest work. Mr. Briggs also claims that he has been successful in producing an aluminium more easily solderable than ordinary commercial aluminium. He claims for the combination superior results to those hitherto obtained.

Bogus Electric Light Men.—A respectably dressed man, who gave the name of Jones was charged at the Westminster Police Court on Friday with being on the enclosed premises of the Westminster School, Dean's-yard, for a supposed felonious purpose. He was seen to enter a room in the building, and when followed and interrogated as to his business, he said he had been sent by a West End firm of electrical engineers, whose name he mentioned, to look after the electrical appliances. He was detained, and inquiries were made of the firm mentioned, who said they knew nothing at all about him. A detective-inspector said that the police had had for the last three years many complaints of larcenies by men calling at mansions and pretending that they were sent to look after the electric light fittings. The prisoner was remanded.

Wilful Damage.—A man named M'Queen was remanded on Tuesday by Mr. Headlam, the Manchester City Stipendiary, on a novel charge of doing wilful damage. On the 20th inst. workmen were laying down an electric light installation at the Mosley Hotel, Piccadilly. A dispute occurred amongst them, and in the course of it prisoner, who had been discharged, is alleged to have torn away the fuse attached to the Corporation main supply, with the result that the hotel, which had been temporarily lighted up, was thrown into complete darkness. The fuses on the staircases leading from the basement were also severed, and it was stated that the hotel, the erection of which has only just been completed, was in great danger of being burnt down owing to the wires coming in contact with the woodwork.

Brewers' Exhibition.—An extensive exhibition of machinery, apparatus, and accessories used in the brewing and licensed victuallers' businesses has been held at the Agricultural Hall during the present week. There is again an almost entire absence of electrical exhibits and lighting, although the exhibition appears to be a favourable opportunity for the display of a variety of electrical appliances suitable for shop, office, and factory lighting, and also for the lighting and fitting of billiard-rooms, public-house bars, &c. There is, however, a good display of engineers' tools and general engineers' stores, made by Messrs. W. H. Wilcox and Co.; Mr. E. S. Hindley shows several examples of small steam engines: and the gas-engine makers are also in evidence. The exhibition has been a very successful one throughout.

Messrs. Drake and Gorham.—This firm have received the contract for installing the electric light in the offices of the Rock Life and Fire Insurance Company in New Bridge-street, E.C.

Messrs. Vaughan and Brown.—We understand that this firm have made arrangements for lighting the Agricultural Hall during the two forthcoming exhibitions, viz., the Confectioners', and the Stanley Shows. The hall is to be illuminated by 50 arc lamps, the current for which will be generated by a Brush dynamo driven by a 20 H.P. gas engine.

Papier-maché Covering for Pulleys.—We have received from Mr. W. S. Dougall, of Radcliffe-on-Trent, some particulars and price-list of his patent pulley covering, which, it is claimed, prevents slipping of pulleys, and consequently saves loss of power from that source.

Messrs. John Wilson and Son.—We are informed that this firm, whose works are at Johnstone, have acquired the works and business of Messrs. William Robertson and Co., machine tool makers, of Johnstone, which they are placing under the supervision of Mr. Alexander Wylie who, for the past thirty years has been connected with the late firm of Messrs. J. and W. Weems. Messrs. Wilson and Son are prepared to continue the manufacture of the various specialities of Messrs. J. and W. Weems, especially those connected with machinery for the manufacture of lead pipes, block tin pipes, sheet lead, and for the covering with lead of electric cables of all kinds.

Messrs. Cox-Walkers.—This firm send us their new catalogue (Part III.), dealing with electric tell-tales, fire alarms, lightning conductors, mining signals, indicators, and bells. Several forms of the specialties are illustrated.

Dynamo Brushes.—The Boudreaux Dynamo Brush Company are introducing into this country their new foliated rolled-metal dynamo brushes (invented by M. Boudreaux, of Paris). Price lists can be obtained at the offices of the Company, St. Martin's House, 1, Gresham-street, E.C. It is claimed for these brushes that they are extensively used on the Continent, that they do not wear away the commutator, keep cool, have a long life, and that by their use, a smooth commutator will run for several days without requiring attention.

Barnet.—The Local Board at their last meeting appointed a committee to inquire into the question of the electric lighting of the town, and to consider the advisability of the Board undertaking the work under their Provisional Order or of transferring their powers to a company.

Bournemouth.—The Town Clerk reported at the last meeting of the Town Council that formal application had been made to the Board of Trade for an electric lighting licence, and it might be expected to be issued in three or four months' time. The Parks

Digitized by Google

Committee had had under consideration the report of the Surveyor, estimating the cost of the illuminating by electricity of the proposed *fountains* in the gardens at £204. 9s. each, and they recommended that the scheme be abandoned. Regret was expressed at the decision of the Committee, and after some discussion, the Surveyor saying that if the proposed illumination were postponed it would be very difficult to carry it out at a subsequent time, it was decided to refer the proposal back to the Committee for further consideration.

BRADFORD.—The Electricity Department of the Corporation report that their income for the past financial year has been £8,399, and the expenditure £3,913, showing a profit on trading account of £4,486. Sinking fund and interest charges amount to £2,863, leaving a net profit for the year of £1,623. The working of the department for the previous year resulted in a net loss of £354, which, deducted from the present year's net profit, leaves a total net profit on the two years' working of £1,269.

CAMBERWELL.—Mr. Manville some time since having been appointed by the General Purposes Committee of Camberwell to report to them as to the best means of introducing an electricity supply into the parish of Camberwell, and the report having been presented and read, it was resolved that it should form the basis of a lecture. This was delivered recently at the Camberwell Vestry Hall, and was illustrated by lantern views and experiments.

CASTLEFORD.—The Electric Lighting Committee reported at the last meeting of the Local Board that Mr. Hammond had offered them terms for advising the Board on the best means of lighting the district by electricity, preparing plans, and doing all the necessary work up to the time of making application to the Board of Trade for a Provisional Order. The Board decided to accept Mr. Hammond's offer.

CHELSEA.—The fourth annual report of the surveyor to the Chelsea Vestry (Mr. T. W. E. Higgins) contains the following remarks upon the electric lighting of the district:—"At the beginning of the year the Cadogan Electric Company was supplying electricity without an Order. The St. Luke's (Chelsea) Electric Lighting Company had obtained an Order, but had not satisfied the Board of Trade as to their financial position. The time for satisfying the Board of Trade having expired, the Vestry agreed to an extension of time, so as to enable the St. Luke's (Chelsea) Company—which appeared to be the Cadogan Company under another name—to satisfy the Board of Trade. They did not, however, do so, and as complaints were received of failure to supply light, the Board of Trade, after receiving a representation from the Vestry, cancelled the Order, and the Chelsea Electricity Supply Company are now supplying the houses formerly supplied by the Cadogan Company. As regards the cancelling of this order, the action taken by the Board of Trade is considered most satisfactory. It has always seemed to be a mistake to have allowed a private company, acting without statutory authority, to break up the public streets, and supply electricity without proper supervision. It is true that the Cadogan Company entered into an agreement with the Vestry, and in virtue of that agreement they opened the streets, but that agreement did not enable the Vestry to control the Company in the supply of electricity, and as a result of this absence of control great inconvenience was caused to most of the persons who obtained their current from this Company. When companies obtain statutory powers to open streets and supply electricity they are, very justly, compelled to fulfil certain obligations in return for their privileges; but under their agreement with the Vestry (which was an illegal one) the Cadogan Company obtained privileges without corresponding obligations being enforced. This Company during some period of their existence were supplying electricity at high pressure. The Board of Trade enforce certain restrictions and regulations upon any company which obtains an Order or Act of Parliament before supplying electricity, and the irregulations as regards a high-pressure supply are of great value for the public safety; but as the Cadogan Company had no licence, Order, or Act, no restrictions or regulations were enforced, or could be enforced, by the Board of Trade, except as regards their overhead wires, and the Vestry had no means of knowing whether the supply of electricity by that Company was at a constant voltage, whether it varied, or whether any attempt to regulate the supply was made."

CHURCH LIGHTING.—The church of St. Mary-at-Hill, in the City of London, is to be lighted by the electric light.

CLECKHEATON.—The Local Government Board have sanctioned the borrowing of £670 for the electric lighting of the public offices.

CLERKENWELL.—At the last meeting of the Vestry a letter was read from Mr. Emile Garcke on behalf of the County of London Electric Lighting Company, asking the Vestry to reconsider their decision refusing consent to the extension of time for carrying out the provisions of their Lighting Order, and stating that the work would be commenced in January or February next. The Vestry, however, decided to adhere to their former decision, viz., that consent would not be given until there were absolute indications of the work having been started.

DEWSBURY.—At the last meeting of the Board of Guardians the Sub-Committee appointed to consider the electric lighting of the Union premises recommended that an electrical expert be engaged to advise the Board, which was agreed to.

EALING.—The Local Government Board inquiry into the application of the Local Board for permission to borrow £25,000 for the purposes of the electric lighting of the district was to have been held yesterday (Thursday).

FALMOUTH.—Messrs. Veale and Co. (Limited) have prepared a report for the Town Council on the electric lighting of the principal streets of Falmouth, and it will be taken into consideration at an early date.

FLEETWOOD.—At the last meeting of the Improvement Commissioners the Clerk reported that the Board of Trade had granted a further extension of six months from the 20th inst. of the Fleetwood Electric Lighting Order. The report of the Lighting Committee, which had been delayed in consequence of illness, was presented. The committee were anxious, seeing that the installation would cost some thousands of pounds, that nothing should be done until they had before them a scheme, which would benefit the town and be a source of revenue. They had now formed an idea of what was suitable for Fleetwood, and they hoped within a very short time to be able to lay before the Board tenders for a complete scheme for public and private lighting at less cost than had yet been effected in any other town, and which at the same time would be second to none in efficiency. The report suggested that the central station should be erected in the Town's-yard, that the present street lamps be used as far as possible for electric lighting, and that a low-tension system with accumulators form part of the scheme, the motive power to be obtained by means of producer gas. The report was accepted, and it was anticipated that the whole matter should be placed before a public meeting after the Board had considered the scheme.

GRIMSBY.—The Public Light Committee of the Grimsby Corporation resolved on Monday to agree to a request from Mr. Hammond that he be allowed to attend before them and explain his views upon the subject of electric lighting. The interview is to take place to-day (Friday).

HALLE (GERMANY).—The Halle electric tramway, the property of the Allgemeine Elektricitäts Gesellschaft, is to be sold to the Halle Tramways Company for 800,000 marks (about £40,000). This does not include permanent way and depot, which belong to the town. A further sum of about £18,500 is to be paid for the electrical plant on the Company's lines.

HALIFAX.—The Town Council have confirmed the minutes of the Gas and Electric Lighting Committee declining the terms on which the Halifax Mutual Electric Light and Power Company proposed to continue the supply of the electric light for 12 months, whilst the Corporation scheme was being installed.

HAMILTON.—The Caledonian Electric Supply Company having requested the Town Council to approve their application to the Board of Trade for a Provisional Order, the Council have decided to withhold their consent, and to apply for an Order themselves.

HANLEY.—The Town Council have adopted a plan, prepared by the Borough Surveyor, providing for the extension of the electric light mains at a cost of £3,100, £1,800 of which is provided for in the existing contract.

HUDDERSFIELD.—The report of the Electric Lighting Committee submitted to the last meeting of the Town Council contained the following:—"The following report submitted by the engineer was approved: The sub-committee appointed, consisting of the Mayor, Chairman, and Vice-Chairman, visited London on October 3rd, and proceeded, with Councillors Sterry and Munroe, to the works of the Indiarubber, Gutta Percha, and Telegraph Works Company (Limited), Silvertown, where the electric light cables were very carefully tested, and found to have an insulation resistance below that specified. The cables have, therefore, been rejected, and others are being made. The Mayor, Chairman, and Vice-Chairman, on the following day, visited the works of the Brush Electrical Engineering Company (Limited), at Loughborough, and examined the new plant which is in course of preparation. Considerable surprise was expressed at the backward state of the plant, which it seems scarcely probable can be at work by the end of October, which is the time specified. Instructions were, therefore, given to the engineer to write the Brush Company and remind them of the fact that they were under a heavy penalty to deliver by the time specified." The minutes of the Committee were confirmed by the Council.——Messrs. Winfields (Limited) have just completed the fittings for the electric lighting of the Town Hall and municipal buildings, including a number of handsome brass electroliers, which have been carefully designed in perfect harmony with the decorations of the buildings.

KILLARNEY.—The dispute as to the lighting of the town reached a further stage on Saturday, when at a meeting of the Town Commissioners, the Chairman signed the minutes of the proceedings of

Digitized by Google

the previous meeting at which the tender of the gas company was accepted, nothwithstanding that the Killarney Electric Light Company had tendered at a much lower figure. A written protest was handed in by a member, and legal proceedings are threatened. ——The Board of Control at Dublin having been requested to supply the Governors of the Killarney District Lunatic Asylum with the reason why the former Board had declined to sanction the scheme for lighting the Asylum by electricity, have replied that they did not feel justified in sanctioning the installation, which would involve considerable expense, until the Company who made the proposal had completed the necessary works for supplying the current required. The Board of Control say, in addition, that they are fully alive to the many advantages of lighting the Asylum by electricity, and they will be prepared to reconsider the project when the Electric Light Company are in a position to satisfy them on the point referred to.

LARNE.—The Town Commissioners sat specially on Friday to consider tenders for the lighting of the town which had been received from Messrs. J. E. H. Gordon and Co. (offering to renew the electric lighting) and from the Gas Company; but neither offer being on the basis of the Commissioners' specification, the tenders were not considered, and the two Companies are to be given until the first meeting of the Commissioners in December to prepare fresh tenders.

LIVERPOOL.—At the annual meeting last week of the Junior Reform Club a general desire was expressed that the club should be lighted by electricity, and the attention of the new committee was drawn to the matter.

QUEENSTOWN.—Negotiations are proceeding between an electric light supply company and some of the ratepayers of Queenstown with reference to providing the town with electric light, and the matter will probably come up before the Public Commissioners in a short time.

POPLAR.—At the last meeting of the Board of Works a letter was read from Mr. Cooper, stating that the Poplar Electric Lighting Supply Company were willing to take a transfer of the Powers granted to the Board by the Poplar Electric Lighting Act under the usual conditions. The Company would pay the Board £250 for cost of securing those powers, and would also pay the cost of the transfer, and would take upon themselves all the powers and liabilities incurred by the Board under the Order. The Board would also have the option of purchasing the undertaking, subject to reasonable notice.

SOUTHAMPTON.—The Harbour Board have appointed Mr. Geo. E. Taylor as engineer in charge of the two electric cranes on the Town Quay.

TOWCESTER.—An endeavour is being made to introduce the electric light into this town, and as the result of a canvass of the principal inhabitants and shopkeepers there seems no doubt but that further steps in the matter will soon be taken.

YEADON.—The Local Board have applied to the Local Government Board for a Provisional Order for power to light the town by electricity, and have also applied for sanction to borrow £7,000 for this purpose.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

October 4, 1893.

18,596. W. MARTIN. Birmingham. Improvements in the means or mode of protecting insulators as employed for electrical purposes or appliances.

18,602. C. D. ABEL. London. Improvements in telephone switchboards. (Société Générale des Téléphones, France.)

18,609. J. G. FOSTER. London. Improved telephone attachment.

COMPANIES' MEETINGS.

Eastern Extension, Australasia and China Telegraph Company (Limited).

The following is the report of the Directors for the half-year ended June 30, 1893, to be submitted to the fortieth ordinary general meeting, to be held at Winchester House, Old Broad-street, E.C., on Wednesday next, November 1st, at 2 o'clock:—

The gross receipts for the half-year ended June 30, 1893, including Government subsidies, have amounted to £257,986. 13s. 5d. against £246,988. 16s. 6d. for the corresponding half-year of 1892. The working expenses, including £21,649. 3s. 3d. for cost of repairs to cables and expenses of ships, absorb £78,229. 19s. 3d., against £79,281. 11s. 10d. for the corresponding period of 1892, leaving a balance of £179,756. 14s. 2d. From this is deducted £3,968. 15s. 5d. for income-tax, £32,171. 1s. 1d. for interest on debentures, debenture stock, contribution to sinking fund and special expenditure, leaving £143,616. 17s. 8d. as the net profit for the half-year.

Two quarterly interim dividends of 1½ per cent. each, amounting to £62,500, have been paid for the half-year under review, leaving £81,116. 17s. 8d. to be carried forward.

The working of the Australian tariff arrangement for the second year of guarantee ended April 30th last, has resulted in a loss of £43,558 as compared with £55,040 for the first year, and in accordance with the terms of the agreement, one-half of the loss or £21,779 has been made up by the guaranteeing Colonies and the other half borne by the associated companies.

Your Directors have to record with deep regret the lamented death, on May 7th last, of their much esteemed and valued colleague Sir James Anderson, who had been connected with the Company since its formation. Under the powers given to them by the Articles of Association they have elected Sir Albert J. Leppoc Cappel, K.C.I.E., to fill the vacancy thus occasioned.

Your Directors have to report that the Chairman having performed the duties of Managing Director since the death of Colonel Glover in 1891 without salary, they have added to the Chairman's remuneration the salary formerly paid to the Managing Director, in consideration of the ever increasing duties and responsibilities falling upon the management.

The Company's maintenance ships have, as usual, been employed on various cable repairs during the half-year under review; but owing to most of the cables being duplicated, the revenue has in no instance been materially affected.

Monte Video Telephone Company (Limited).

The following is the report of the Directors, to be presented to the shareholders at the annual general meeting, to be held at the offices, No. 96, Gresham House, Old Broad-street, E.C., on Tuesday, October 31st, at 12 o'clock:—

Your Directors present herewith the audited statement of accounts for the year ended July 31st last, showing a net profit for that period of £6,895. 17s. 6d., which, including the amount of £1,879. 5s 3d. brought forward from last year, leaves an available balance of £8,775. 2s. 9d. after providing for all working expenses in Monte Video and London, and after writing off £49. 18s. 7d. for proportion of preliminary expenses, and

Digitized by Google

£35. 5s. 8d. for depreciation of furniture at head office and in Monte Video. A comparison of the present accounts with those of last year shows a decrease of £1,100 in the working expenses at Monte Video, and of £275 in the London office expenses, making together a decrease in expenses of nearly £1,400, while the falling-off in the total value of subscriptions is only £700, and the net profit for the twelvemonth, after making ample allowance for bad and doubtful debts, is close on £500 more than for the preceding like period. Considering the continued state of depression prevailing in business circles in Monte Video during the whole of the period under review, your Directors think these figures will appear to you satisfactory under the circumstances.

The central premises in Monte Video have now become the unencumbered property of your Company, the final instalment of the purchase, money having been paid on March 6th last. The total sum paid out of this year's earnings for purchase-money and interest is £5,504, and in addition to this expenditure it has been deemed expedient to open up a new branch to Barra, a small hamlet, distant about ten miles from Monte Video, at the mouth of the river Sta. Lucia, and other new lines have been laid at the request of subscribers, so that the total outlay for improvements and additions to your property stands at £1,637, making together £7,141 paid out of revenue: therefore the Directors do not think it advisable to declare any dividend, and they recommend that the sum of £5,000 be placed to the reserve account, that £3,000 be added to depreciation fund, and that £775. 2s. 9d. be carried forward to next year.

The number of paying subscribers is now 1,383, showing an increase for the year of 53, and with a return to more normal conditions in commercial circles generally in Uruguay, there is no doubt this number would be substantially increased.

The Directors have to announce that the Committee of the London Stock Exchange granted, on June 12th last, an official quotation to this Company's shares, both Preference and Ordinary.

It having been suggested by several large shareholders that a fourth Director might be added to the Board, this matter will be submitted to the meeting for consideration. In accordance with the Articles of Association, Mr. E. F. Powers retires *per rotâ* from the Board, and, being eligible, offers himself for re-election. The auditors, Messrs. Gérard Van de Linde and Son, also retire, but offer themselves for re-election.

NEW COMPANIES, STATUTORY RETURNS, &c.

CANTERBURY ELECTRICITY COMPANY (LIMITED).—This Company was registered on October 18th, with a capital of £50,000, in £5 shares, to carry on the business of electrical engineers, electricians, suppliers of electricity, contractors, mechanical and chemical engineers, and of producing light, heat, sound, motive-power, or other force by electricity, galvanism, magnetism, or otherwise, and to manufacture or deal in plant, machinery, implements, &c., relating to the objects of the Company. The subscribers are:—

	Shares.
B. Broadhurst, Minerva-road, Kingston-on-Thames	1
George E. Zeden, Shandon Lodge, Coventry Park, S.W.	1
Frank E. Beeton, 76, Woodsome-road, N.W.	1
F. Hodson, 161, Kennington-road, S.E.	1
W. D. Brightman, 7, Queen Anne-terrace, Bowes Park, N. ...	1
R. Percy Sellon, 49, Queen Victoria-street, E.C.	1
A. J. Lawson, 63, Bedford-gardens, Kensington, W.	1

The number of directors is not to be less than three nor more than seven.

DOVER ELECTRICITY COMPANY (LIMITED).—This Company was registered on the same date, and with the same amount of capital, similar objects, and the same signatories, as the Canterbury Electricity Company (Limited), given above.

ENGLISH ELECTRIC MANUFACTURING COMPANY (LIMITED).—This Company was registered on October 23rd, with a capital of £5,000, in £1 shares, to carry on the business of electrical and mechanical engineers, electricians, suppliers of electricity, and manufacturers of, and dealers in, electric, galvanic, magnetic, telegraphic, telephonic, and other appliances and apparatus; to generate, produce, accumulate, transmit, distribute, and supply electricity, magnetism or similar agency, for all purposes for which the same may be used; to erect, fix, lay down, construct, connect, provide, supply, let on hire, remove, and keep in repair, cables, wires, lines, dynamos, accumulators, meters, fittings, lamps, &c.; and generally to carry on the business of an electric apparatus manufacturing and electricity supply company in all or any of its branches. The subscribers (with one share each) are:—M. J. St. C. Griffin, Liverpool; John H. Hirst, Huddersfield; Joseph Hales, Leicester; Archibald Anderson, Southport; J. W. Parsons, Cardiff; F. H. Lloyd, Mansfield; M. N. Hales, Leicester. Joseph Hales is the Chairman of Directors.

GEORGE ADAMS AND SONS (LIMITED).—This Company has been registered with a capital of £100,000, in £10 shares, to acquire the business of galvanised iron and steel manufacturers and ironmasters, carried on by George Adams and Sons at Bilston.

HART, SON, PEARD AND CO. (LIMITED).—This Company has been registered with a capital of £35,000, in £10 shares, to acquire, as a going concern, and carry on, the business of ironmongers, iron and brass founders, metal workers, &c., as now carried on at Birmingham and London under the style of Hart, Son and Peard.

RAMSDEN, CAMM AND CO. (LIMITED).—This Company has been registered with a capital of £50,000, in £10 shares, to acquire the business of wire drawers, manufacturers, and galvanisers, carried on at Brighouse, Yorks, under the styles of Ramsden, Camm and Co., and S. H. Byrne, and to carry on the business of wire drawers, manufacturers and galvanisers, iron and brass founders, metal workers, mechanical engineers, machinists, &c. The first Directors are Isaac Lancaster, William H. Shepherd, Joseph Hey, Hophni Bland, and one other to be elected by the above-mentioned Directors.

WILLIAM MUIR AND CO., MANCHESTER (LIMITED).—This Company has been registered with a capital of £80,000, in £5 shares, to acquire the business carried on at Strangeways (Manchester) and elsewhere by William Muir and Co., and the works and property held therewith, and to carry on the business of machinists, machine and engineering tool makers, mechanical engineers, iron and brass founders, metal workers, &c. The first Directors are A. Muir, H. Garnett, and F. H. Garnett, A. Muir being Managing Director.

ELECTRIC FITTINGS HIRING AND MAINTENANCE COMPANY (LIMITED).—The first annual return of this Company, made up to August 21st and recently filed, shows that only the seven signatories' shares had been taken up out of a nominal capital of £200,500, divided into 40,000 Ordinary shares of £5 each, and 500 Founders' shares of £1 each. No calls have as yet been made.

ELECTRO-AUTOMATIC FIRE EXTINGUISHING COMPANY (LIMITED).—In reply to official inquiries as to the cause of the non-filing of the necessary returns, Messrs. Fox and Joy, of 59 and 60, Chancery-lane, London, W.C., write stating that General Marten, the promoter and vendor, left England immediately after the incorporation of the Company, and the very *raison d'être* ceased to exist in consequence.

ENGLISH ELECTRIC CARBON COMPANY (LIMITED).—The annual return of this Company, made up to July 24th, and recently filed, shows that 641 shares have been subscribed for and allotted, out of a total nominal capital of £10,000, in £10 shares. Upon 56 of these the full amounts have been called, and upon the remaining 585 shares a call of £5 per share has been made, resulting in a total payment of £3,485.

EXETER ELECTRIC LIGHT COMPANY (LIMITED).—The annual return of this Company, made up to October 7th, shows that out of a nominal capital of £20,000, in £10 shares, 1,100 shares have been taken up, of which 305 have been issued as fully paid. Upon the remaining 795 shares the full amounts have been called and paid. By special resolutions passed on September 23rd, and confirmed on October 14th, 500 Ordinary shares which were not issued were changed to "A," or Preference, bearing interest at 6 per cent. per annum, and the Articles of Association were altered in accordance therewith.

CITY NOTES, &c.

BRIGHTON AND HOVE ELECTRIC LIGHT COMPANY (LIMITED).—Suggestions were made at a recent meeting of the Debenture-Holders' and Creditors' Committee that a scheme for the reconstruction of the Company should be formulated, and we have received a copy of the proposed scheme. The subscribed capital and liabilities of the present Company are:—Ordinary shares of £5 each, in £15,005; First Mortgage Debentures, £15,000; unsecured liabilities, (about) £8,500; or a total of 38,505. Under the proposed reconstruction scheme the present shareholders are to submit to a reduction of the £15,005 in Ordinary shares to £7,505, entitling the holders to any profits after providing for interest on debentures and dividends on the two proposed classes of Preference shares; the creditors on unsecured accounts are to be allotted Second Preference shares to the value of their claims on outstanding accounts, entitling holders to a 6 per cent. dividend, after providing interest on debentures and for dividend on First Preference shares, and to rank in priority to the Ordinary shares as regards capital; the debenture-holders are to surrender half their holding in Debenture bonds, viz., £7,500, and to receive in exchange £7,500 in First Preference shares, in addition to shares for arrears of interest entitling holders to a dividend at the rate of 6 per cent. per annum after payment of interest on debentures, and to rank in priority to the Second Preference and Ordinary shares as regards capital; and £5,000 is to be raised in new capital on Six per Cent. Prior Lien Debenture Bonds, which will rank as a first charge on the property and undertaking of the Company in priority to the £7,500 debentures retained by the present debenture bondholders. The total subscribed capital of the Company under this reconstruction scheme would thus be £37,005.

CALLENDER'S BITUMEN TELEGRAPH AND WATERPROOF COMPANY. The Directors of this Company have declared an interim dividend (payable on November 1st) at the rate of 10s. per share.

CITY AND SOUTH LONDON RAILWAY COMPANY (LIMITED).—The traffic receipts for the week ended October 22nd were £807, as against £865 for the corresponding period of last year, being an decrease of £58. The total receipts for the half-year amount to £12,918, against £12,620 in the corresponding period of 1892, being an increase of £298.

CONTINENTAL ELECTRICAL DIVIDENDS.—The Geneva Electricity Works last year made a profit of over 300,000fr. (about £12,000); after placing about £7,000 to reserve the dividend is 5½ per cent. The Stettin Supply Company pays 5½, against 4¾ per cent. last year. The Berliner Elektricitäts Gesellschaft distributes 8½ per cent., against 7½ per cent. last year.

INDO-EUROPEAN TELEGRAPH COMPANY (LIMITED).—The Board of Directors of this Company have declared an interim dividend for the half-year ended June 30th last at the rate of 5 per cent. per annum, free of income-tax, payable on and after 1st proximo.

PRETORIA LIGHTING COMPANY (LIMITED).—The Directors' report presented to the fourth annual meeting of this Company, held at Pretoria,

Digitized by Google

on September 1st, showed a profit on the year's working of £2,000, which was considered highly satisfactory. The electric light was growing in favour, and nearly every important building in the town was supplied with current by the Company. The report and accounts were adopted.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).—The traffic receipts for the week ended October 20, 1893, after deducting 17 per cent. of the gross receipts, payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,493.
